Lectures and Addresses.

LECTURES ON

HUMAN AUTOMATISM.

DELIVERED AT THE LOWELL INSTITUTE, BOSTON.

By WILLIAM B. CARPENTER, M. D., LL. D., F. R. S., Etc.

LECTURE I.

The Question Stated.—Is the Body of Man the Minister and Instrument of his Mind; or is his Mental Action a function of his Bodily Organization? Relation between Mental Activities, or *Psychoses*, and Physical Changes in the Nervous System, or *Neuroses*. Analogies between Bodily and Mental Automatism. Testimony of Consciousness to the Independent Personality and Self-directing power of the *Ego*: how far is this trustworthy?

Of all the philosophical questions on which the intelligent thought of the present generation, and especially of its younger members, is at present exercising itself, there is none that seems to me more fundamental in its character, or more momentous and far-reaching in its issues, than that which I have undertaken to bring before you; and I know this to be the conviction of many who have come here with the desire to learn what light can be thrown on it by one who has made the bodily and mental constitution of man the special study of his life. To such I dare not promise more than *help*. Every student of human nature knows that it contains *penetrabilia* he can not enter, depths he can not fathom. But it is something to learn the limits of our inquiry, and to make clear what the physicist would call its "critical points"; something, too, to find ourselves helped in the pursuit of it by experiences whose very familiarity often prevents our recognition of their importance. And just as the Alpine climber who meets with an obstacle to his direct progress, in the form of a perpendicular precipice or a deep crevice, may find a way round it, so I think I shall be able to show you that we may often reach a safe conclusion by some indirect path, when the direct road is closed against us. And it will be my special object to point out to you that some of these assured convictions which no one ever thinks of seriously calling in question—such, for example, as the certainty which every one feels as to the existence of a world external to himself—rest on a basis not one whit more secure, logically, than that of man's (limited) self-determining power, although this is supposed by many to have been completely exploded by modern scientific research. In there be any among my auditors who think it strange that a physiologist should regard man as the possessor of any measure of moral freedom, and who wonder how an evolutionist can claim for him any higher place in nature than that which he owes to the greater complexity of his automatic mechanism, I would ask them to suspend their judgment until I have shown what seems to me to be the complete conformity of the doctrine I advocate with those fundamental *facts of consciousness* which, in the words of John Stuart Mill, "are much more real than anything else—the only things which we directly *know to be real*"; and which therefore constitute, in my view, the "base of verifi-

cation" to which all our logical triangulation must be worked back in order to test its validity.

The questions we have to consider are, (1) whether man in his entirety is an automaton; and, if not, (2) what part of his bodily and mental activity is automatic, and how his automatism may be directed and controlled. But we have first to frame such a precise definition of that term as may enable us to pursue our inquiry with a clear and distinct conception of the meaning it conveys. Such a definition is not adequately furnished by its etymology; which, as you all know, only implies the power of self-motion. Now, as we are all "self-moving" creatures, we are all in that sense *automata*. But this is not the sense in which the term is used scientifically; and I think that in defining an automaton as "a machine which has within itself a power of action, under conditions fixed for it but not by it," I shall call up in your minds the precise idea which I myself attach to the term, and which I mean to make the basis of our discussion.

This is precisely the view which a certain school of philosophy takes of the nature of man. It regards him as a self-acting machine, whose operation at each moment of its existence is the necessary response of its *then* constitution to external agencies; that constitution being originally determined for him by his "heredity," and subsequently modified by his "environments"—that is to say, by the various influences which have been brought to bear upon him during his whole life, but especially during that early stage of it in which his original constitution is most capable of being modified by external agencies, and in which, by the direction thus given to the processes of growth and development, those modifications tend so to fix themselves in his constitution as to exert a persistent influence upon his whole subsequent existence.

Now, if that be the whole truth of the case, it is clear that man is an automaton, his conduct being in no degree determined by himself, but determined for him by influences which he has no power to control or direct, and for which he is therefore in no degree answerable. Strange as it may seem to many of you, this doctrine is explicitly affirmed to be the only one which a really scientific man can now hold; those who, like myself, attach some value to those facts of consciousness which are to us "more real than anything else, the only things we *know to be real*," being pitied as the victims of a self-delusion which arises out of the erroneous shaping of our early beliefs, and which will soon die out with other exploded errors. It is to me not a little singular that one of the most distinguished members of this school, who now maintains that the state we call volition is not the cause of the motion which follows it, but merely the "symbol in consciousness" of that state of the brain which is the immediate cause of that act (just as the blowing of a steam whistle signals, but does not cause, the starting of a locomotive), should have abandoned the firm position he formerly took, that "man's volition counts for something as a condition in the course of events"—a belief which, he said, "can be verified experimentally as often as we like to try, and which, therefore, stands upon the strong-

est foundation upon which any belief can rest, and forms one of our highest truths."* And I appeal to the consciousness of every one of you whether it does not give you the most distinct and explicit assurance, as often as you like to try the experiment, that your will *has* a power over the movements of your body. Now, when I speak of "the will," I wish you to understand that I mean the *Ego* in action. I do not regard the will as a distinct *faculty*. It is merely that *state* in which the *Ego* is purposely and expressly acting either upon the body or upon the mind. I shall show you by and by what a parallelism there is between these two forms of activity; and I think that you will all recognize it in that "sense of effort" which we experience alike in the performance of bodily movements which are difficult to us, and in the keeping our attention fixed upon some mental object from which some powerful attraction would else withdraw it. That line of thought, however, I shall not pursue at the present moment, as I wish to place before you a case in which purely mechanical automatism and the asserted automatism of human action can be brought into direct contrast.

I have a friend who is accustomed to recreate himself occasionally by playing upon the chamber-organ. You know that the pipes of an organ are made to sound by the blowing of air through them; and that its wind is provided by the action of bellows, which send air into the "wind-chest" from which the pipes are supplied. Now, when the player is using a good many stops there is a considerable demand for wind, and the bellows must be worked quickly; but if he is playing softly on a few pipes, the wind goes out much more slowly, and a very much slower action of the bellows is needed. The quantity of wind in the wind-chest is indicated by a little weight called a "tell-tale," which moves up and down within view of the bellows-blower; and he is thus informed whether a large or small supply of wind—requiring much or little action on his own part—is required. Now, my friend used to be sometimes troubled by the inattention of his bellows-blower—a female servant who was summoned for the purpose. Whether it was that, being charmed with his music, she gave her attention to his performance instead of to the indications of the "tell-tale," or whether her thoughts were occupied in some entirely different manner, I do not know; but she used to vex him not infrequently by letting the wind out (as we call it), so that the sound of the organ would suddenly cease with a very unpleasant sort of expiring sigh. Now, being rather tired of this, and having other reasons for wishing to be independent of a servant, my friend took counsel with a mechanic, and established an automatic bellows-blower, worked by water-power, which should do exactly the same thing mechanically that the human bellows-blower did by voluntary movement, the apparatus being so arranged (I dare say that many of you are acquainted with it, as I believe it is used here, as well as in my own country, for church organs) that the up-and-down movement which works the bellows is more or less rapid as the demand for wind is greater or less. At first this apparatus did not answer very well. Not having been quite

rightly fixed, it worked stiffly, and sometimes would not work at all; but a little "doctoring" on the part of its maker soon set it right, and it has ever since worked to my friend's entire satisfaction. Now, supposing that apparatus to be incased within a human figure; you would then have a real "automaton," which would do, under conditions purely mechanical, exactly the work which the human bellows-blower ought to have done, but failed to do. And the question I have to bring before you is, whether *her* action was really as automatic as that of the machine, so that for her failure to perform the duty with which she was charged she was no more responsible than was the water-blower for the fault of its first fixing. *Her* failure was due not to any defect in her bodily constitution; she had good sight to see the "tell-tale"; she had plenty of muscular strength to work the very easy bellows; she had the knowledge that she was expected to exert this when the "tell-tale" warned her that the wind was low; and she did not contest the obligation to do the work imposed upon her. What, then, was wanting? Simply *the mental determination to keep her attention fixed upon the object*. Here was the "critical point;" for it is on the power which I affirm the *Ego* to possess, of *fixing his attention*, that the regulation, by his personal effort, of all his intellectual, moral, and volitional activities seems to me to depend.

We are told, however, by those who hold the doctrine of automatism, pure and simple, that the human bellows-blower's work could be done just as well if her mind had no concern in it whatever, the train of nervous mechanism supplying all that is really necessary, the will being only the "symbol in consciousness" of the outgoing of her brain power, and her conscious recognition of the call for exertion, with the purposive response to it, being mere "surplusage." According to this view, it was not necessary that she should either *see* the "tell-tale" or *attend* to its movements, the visual impression made by them upon her retina being sufficient to call forth through the optic nerve that change in the nervous center which we call reflex action, and thus to excite the respondent movement through the muscular apparatus. Supposing the nervo-muscular apparatus to be in good working order, not only the working of the bellows, but the regulation of it by the movements of the "tell-tale," might be executed without any more direct participation of *mind* in them than there is in the action of the self-regulating water-blower.

Now, I assure you that this is no parody upon the teaching of the automatist school, but is merely the explicit application of its general doctrine to a particular case. And yet I can not help thinking that you will see that this is one to which our "common sense" refuses its assent—what I mean by "common sense" being that general "resultant" of our experiences upon which we are constantly falling back (as I shall have occasion to show you during this course) as the test of truth and the guide of conduct.

It is remarkable, however, that the views taken of this subject by different members of that school are by no means identical. The late Professor Clifford, who was in some respects the most prominent exponent of it, reproduced in another form the "pre-established harmonies" of Leibnitz,

* Professor Huxley's "Lay Sermons," p. 160.

denying that mental and bodily activities can have any possible relation to each other. In a lecture on Mind and Body, which I myself heard, he maintained that the mental facts go on by themselves, and the bodily facts go on by themselves, as it were, on two different platforms; and affirmed—I quote his own words, that I may not misrepresent them—that, as “the only thing which can possibly be conceived to influence matter is either the position or the motion of surrounding matter,” the statement that “the will influences matter” is simply “nonsense.” In taking this position, Professor Clifford seems to me to have been dominated by his purely physical preconceptions. He was a most accomplished mathematician, and an able physicist, who had gone into the study of psychology with the prepossessions derived from his physical training, and without the correction which the study of physiology, and especially that of the intimate *nexus* between mental and bodily states, would have afforded him. However great was Professor Clifford’s authority upon the subjects he had especially studied, I deny his claim to the knowledge of everything about matter and its relations, and his right to affirm that mankind at large are wrong in the conviction that the movements of their bodies are to some extent directed by their minds. On the other hand, there are eminent members of the automatist school who freely admit, as Professor Huxley once did, that man’s volition determines his bodily action; their contention being that his volition is itself determined *for* him and not *by* him. And Professor Huxley, while now denying that man’s will can prompt his brain to call his muscles into action, still holds to the belief that certain physical changes in his nervous mechanism can call forth those affections of the mind which we call sensations—giving us, in fact, terms which we shall find it extremely convenient to use in this inquiry. He designates that state or affection of the nervous system by which it receives and transmits impressions made on it by external agencies as a *neurosis*, using this term to express the physical affection of the nervous system which is the immediate antecedent of the mental state we call sensation, without going into any question as to what the particular nature of that affection is. Sensation, on the other hand, being a purely mental condition, he very happily (as I think) designates the affection of our consciousness which is called forth by the neurosis as a *psychosis*, and the application of this term may be extended to any other mental affection called up by brain changes, as in the case of those phenomena which I shall hereafter describe under the term “unconscious cerebration.”

Now, as Professor Huxley, in his latest (Belfast) lecture upon this subject, distinctly affirmed it to be a fact, based on the normal experience of healthy men, which we may verify experimentally as often as we choose, that running a pin into one's finger produces that unpleasant sensation which we call a prick—such *psychosis* being, in the normal or healthy condition of man's organism, the uniform sequence of that particular *neurosis*—I find myself quite unable to understand why, in that same lecture, he should have denied the converse proposition which he had previously affirmed (by implication) upon the very same basis of universal experience—namely, that in the performance of a voluntary

act a *psychosis* calls forth a *neurosis*. To me it still seems clear that, in the act of "willing," the determination by the *Ego* to execute a given movement expresses itself in the nervous change which calls forth the muscular contraction; the sequence of the *neurosis* upon the *psychosis*, in this case, being just as constant as the sequence of the *psychosis* upon the *neurosis* in the other.

Again, Mr. Herbert Spencer and Professor Huxley alike take their stand upon the doctrine of the universality of causation as consisting in unconditional sequence—a doctrine which every man of science accepts in regard to physical causation, but which seems to me utterly inapplicable to mental phenomena, which can not be reduced to any common measure with material changes. When Professor Huxley, in his Belfast lecture, spoke of man as nothing but “a part of the great series of causes and effects which, in unbroken continuity, composes that which is, and has been, and shall be—the sum of existence,” I have no doubt that he expressed Mr. Herbert Spencer’s conviction as well as his own.

Now, what seems to me the inevitable corollary from this doctrine was explicitly set forth in the correspondence published many years ago between Miss Martineau and Mr. Atkinson. I quote their words, because they express, more concisely and perspicuously than any others I have met with, what I think any one who considers the matter must see to be the necessary deduction from the purely automatist view of the case. "I am what I am : a creature of necessity ; I claim neither merit nor demerit." "I feel that I am as completely the result of my nature, and impelled to do what I do, as the needle to point to the north, or the puppet to move according as the string is pulled." "I can not alter my will, or be other than what I am, and can not deserve either reward or punishment."

Such is the doctrine of which the consideration forms the special subject of this course. And the view to which I shall endeavor to lead you is this: that, while there is great deal of truth in it, we can not accept it as the whole truth; that while a great deal of our mental as well as bodily action *is* determined by our heredity, by the conditions of our education, and by the environments in which we subsequently find ourselves—that, in fact (as John Stuart Mill was accustomed to maintain), what a man will do in any particular juncture may be predicated from his formed character—yet that (as he came explicitly to admit)* man has a power over the formation of his character. I shall endeavor to show you that, in shaping the course of his conscious life, man has a power of self-determination, which depends essentially upon the *fixation of his attention* upon

[illegible]

the motives which automatically present themselves before him; thus giving a preponderating effect to those which he knows *ought* to prevail. Toward this conclusion everything I shall bring before you will lead more or less directly; so that in the end you will find it so completely in harmony with a number of separate and independent probabilities as not only to justify but to require our acceptance of it, notwithstanding that it may seem to be negated by what is called logical proof—the fallacy of which seems to me to lie in its fundamental assumption of the identity of moral with physical causation.*

Now, in what remains of our present meeting, I wish specially to bring before you the question of the relation of our mental to our bodily organism. Every one feels that he has a mind and a body; and every one knows, when he comes to think about it, that he is *directly* conscious of what is taking place in his mind, while he is only *indirectly* conscious of what is taking place in his body; and thus he comes to regard his mind as his true *self*, and to look upon his body as external to that self. Although we refer our sensations to particular localities in our bodies, yet it is not in our bodies, but *through* our bodies, that they are really felt as affections of the conscious mind. Thus, when we speak of feeling the prick of a pin in the finger, what we really feel is a change in our own state of sensorial consciousness; and this change we are led by the automatism of our constitution to refer to a certain part of our bodily fabric in which it seems to ourselves to have originated. I must not now go into a discussion of the mode in which we arrive at this or many similar conclusions; but shall have to appeal constantly to the individual experiences of each one of you, and to the fundamental facts of his (or her) own consciousness. And those (if such there be) who expect me rather to adduce some striking and novel phenomena than to go over ground already so thoroughly trodden, may be asked to recollect that it is only by an appeal to the individual consciousness of each of my hearers that I can hope to lead him (or her) to my own conclusions upon these points; because no one can make the consciousness of another *his* consciousness. Every one thinks and feels for himself. He may, to a certain degree, come to know what another person is thinking and feeling; but no one can ever penetrate the thoughts and feelings of another fully and entirely, however intimate his relation to that other may be. He can only judge of the thoughts and feelings of another by those outward manifestations of them which come to him through that other's movements, are perceived through his own sensations, and are then interpreted through his own intellectual and emotional sympathies.

The relation between our minds and our bodies is maintained through that wonderful piece of organic mechanism—the nervous system. And this mechanism has two principal modes of operation: one, that by which it makes us aware of what is taking place in the external world (including our own bodies, which, as I have just pointed out, are really external to our mind), through the apparatus of

* "In itself," says Professor Huxley ("Lay Sermons," p. 160), "it is of little moment whether we express the phenomena of matter in terms of spirit, or the phenomena of spirit in terms of matter."

sensation; the other, that by which it expresses the determination of the mind, through its power over the apparatus of motion (I confine myself for the present to the *volitional* determination, the power which the Ego possesses of calling forth purposive muscular movement). You know that the muscular apparatus is that by which the limbs and other movable parts of our bodies are put into action, those muscles acting upon a set of bony levers which constitute the skeleton; and, in fact, the aggregate of the *nervo-muscular* apparatus (including the organs of sense and motion) would—if it could sustain itself—be *the man*.

But it is impossible that such should be the case. A great and complicated apparatus is necessary for the building up, in the first place, and for the subsequent maintenance, of this wonderful fabric, of which the nervous system constitutes the center, being the part with which our minds are in immediate and direct relation. The nature of that relation—the mode in which a *neurosis* gives origin to a *psychosis*, or a *psychosis* produces a *neurosis*—is the great fundamental problem of our dual nature, a mystery which I scarcely expect that any one will ever solve.

(To be concluded.)

Original Communications.

CARBOLIC ACID IN THE TREATMENT OF WOUNDS.

By WILLARD PARKER, M. D.,

EMERITUS PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

In limiting my remarks to carbolic acid, I wish to be understood as referring to that agent chiefly as the representative of a class of antiseptics, germicides, etc., which have come into use within the past few years in the treatment of wounds, more or less in conformity with the doctrines and practice taught by Professor Lister. I single it out for the reason that it is better known by the profession, and more closely bound up, so to speak, with what we speak of as Listerism, than the other drugs that are used for like purposes. Furthermore, since antiseptic surgery did not come into vogue until after I had in great measure withdrawn from the active practice of surgery, I would premise that my impressions in regard to its value are drawn not so much from my own personal experience with it as from a comparison of the results which it now enables my younger colleagues to obtain with those which were secured in the practice of surgery during the many years that I was busily engaged in surgical work before anything was known of the Listerian system.

I will state, at the outset, my decided conviction that the use of carbolic acid is a valuable adjuvant in surgical practice. As a mere disinfectant, carbolic acid seems to me to be in no way superior to a number of other agents, but probably inferior to some of them; as an antiseptic and detergent, however, I am inclined to believe that it is not surpassed by any other substance. As to its supposed spe-

efficacy property of allaying or antagonizing the inflammatory process, apart from its antiseptic action, my impression is that the stock of well-ascertained facts now at our command is too small to warrant our drawing any decided conclusion. It is to its germicidal properties, in my opinion, that its efficiency in averting inflammatory complications is mainly due. It is valuable also as a topical stimulant to ill-conditioned suppurating surfaces, such as the walls of cold abscesses and the like, in patients broken down in health.

As a matter of course, a germicide is needed only under circumstances that make it a reasonable inference that morbid germs are actually present in the air about the patient, or in the implements and appliances that are used in dressing the wound; carbolic acid, therefore, is of the most signal advantage in the case of patients who have to be treated in close, ill-ventilated rooms, or within the range of exhalations from diseased surfaces in other patients—or, in general terms, under any circumstances in which the sufferer is compelled to breathe a confined atmosphere, perhaps contaminated with morbid animal effluvia. The use of this agent must, therefore, be eminently valuable in the treatment of the wounded in hospitals, in tenement-houses, and in other localities of a like unfavorable hygienic character.

I am not yet convinced that the use of the spray is of any direct advantage, especially in cases where the patient's constitution and general health are such as they should be, and the wound is kept perfectly clean; but there can be no doubt, I think, that not only the spray, but also every one of the many minutæ that are associated with Listerism, are of the very greatest benefit, in an indirect way, by calling the attention of the operator, of the assistants, of the bystanders, and of the nurses, all, in short, who are in any way connected with the patient's personal surroundings, to the never-ending necessity of that cleanliness which is next to godliness—calling their attention to this necessity, and keeping it fixed there throughout the whole course of the case.

On the whole, it does not yet appear to me that operative surgery, leaving out of account those operations in which the abdominal cavity is opened, is more successful under Lister's method of practice than it used to be before that system came into use; certainly, in the case of clean wounds, well cared for and treated in the country, it is my decided impression that no better results can be got with Listerism than without it. In saying this, I do not lose sight of the fact that, no matter how favorable the surroundings may be, pent-up and putrescent material in volves terrible dangers. Under such circumstances carbolized injections are unquestionably of the greatest value, but from this point of view there is nothing new about antiseptic surgery; in former times the chlorine preparations and other detergents and antiseptics doubtless proved equally efficient preventives of septicæmia.

Like everything else that has the charm of novelty, the use of carbolic acid has been pushed, I believe, beyond the limits that will in the future be set upon it; at present the strict measure of its value does not seem to me to be fully settled, nor has it been quite determined under what circumstances it should or should not be resorted to. I am not yet convinced that its employment is imperative as a

routine measure, but am quite willing to concede to it the character of a most valuable resource in cases that plainly call for it.

ANTISEPTIC SURGERY.

By H. B. SANDS, M. D.,

PROFESSOR OF THE PRACTICE OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, SURGEON TO THE ROOSEVELT HOSPITAL.

IN the brief remarks which I am allowed to make in the present communication, I propose to discuss the question of antiseptic surgery under the following headings, namely: 1. Principles. 2. Methods. 3. Results.

1. *Principles*.—On this topic my views are perhaps entitled to little weight, as I have never made it the subject of original experimental investigation. But an extensive experience in the management of wounds according to Lister's method, and other similar methods, has convinced me that their success is mainly due to their agency in preventing putrefaction. Other explanations have, however, been offered by able observers. Markoe believes that the beneficial influence exerted by the local application of carbolic acid depends on a specific power which it possesses "of modifying vital actions" and "controlling inflammation." This statement appears to me somewhat unsatisfactory. A more definite explanation is offered by Prudden, who, having proved by experiment that certain antiseptics—namely, carbolic acid and salicylic acid—hinder the amœboid movements of the white blood corpuscles, and retard or prevent their emigration from the blood-vessels, suggests that the efficacy of these substances in the treatment of wounds may be due in part to their action in lessening suppuration, so far as this depends upon cell emigration and not upon cell-proliferation. A serious objection to this view is the clinical fact that the direct and continued application of carbolic acid to wounded surfaces promotes suppuration, and so far retards recovery. Perhaps no theory on this subject is beyond criticism; but, in the present state of our knowledge, that offered by Lister seems to me the least objectionable. The contrast between the behavior of a subcutaneous lesion and an open wound left without protection can be explained only by the occurrence of putrefactive changes in the latter, and their absence in the former; and the fact that wounds which run an aseptic course are comparatively free from danger is undeniable. I also accept, without reserve, the germ theory of putrefaction, and believe that, when this kind of decomposition occurs from an open wound, it is caused by the entrance of air containing solid particles which act as ferments. That this action is not invariable, and that, even when germs are freely admitted to wounds, their putrefactive power is neutralized whole or in part by the living tissues, may be conceded without denying the agency of these bodies in causing putrefaction under favorable conditions, as, for example, when secretions are retained in a wound to which atmospheric air is admitted. The aim of antiseptic surgery is simply to prevent these putrefactive changes.

2. *Methods*.—I have the honor to acknowledge that, as strictly scientific, and as an admirable adaptation of the principles on which it is founded, it seeks to exclude the living

germs or ferments from the wound, thereby preserving it aseptic; and no pains are spared to accomplish this result. The minute details and precautions insisted on by Lister have excited opposition and ridicule; yet they are the logical outcome of the theory which underlies his practice. And I gladly testify, from personal experience, to the excellence of this method, which, when it can be thoroughly carried out, is almost uniformly successful. But it is troublesome, complicated, and expensive. In common with many others, therefore, I have sought simpler and cheaper methods. For several years past I have substituted irrigation for the spray, without any apparent disadvantage. I have almost invariably employed carbolic acid for disinfecting the hands, the instruments, and the wound during operations, believing this antiseptic to be superior to all others for this purpose. As a dressing for wounds that can be closed, I have found nothing equal to iodoform. A piece of iodoform gauze—10 per cent.—six to eight layers in thickness, is laid over the line of union. Over this is placed a thick pad of salicylated absorbent cotton, then a piece of gutta-percha tissue, and finally a bandage. After operations involving such loss of integument as to prevent closure of the wound, I have used as applications to the raw surface carbolized oil (1 to 10), iodoform gauze, naphthalin, and an aqueous solution of corrosive sublimate, 1 to 2,500. Of these, the one last mentioned possesses many advantages. It is odorless, highly antiseptic, and, so far as I am aware, causes no toxic symptoms, even when used in considerable quantity.

As a rule, I employ catgut ligatures which have been soaked for several months in carbolized oil. Silk ligatures, prepared by being boiled in a five-per-cent. solution of carbolic acid, as recommended by Czerny, I have used extensively, and have generally been satisfied with the result. They are stronger than catgut, and are more easily tied. But occasionally they act as foreign bodies, and cause abscesses after the wound has healed; and on this account I have nearly abandoned their use in wounds that are expected to unite by adhesion. The same objection applies to catgut ligatures which, according to a recent suggestion made by Lister, have been treated with a one-per-cent. solution of chromic acid, and afterward with sulphurous acid. These, according to my observation, often fail to undergo absorption, and act as irritants. A firm but soluble catgut ligature, which can be kept dry until needed for use, is still a desideratum. Am Ende, of Hoboken, lately sent me some samples of dried catgut which had first been soaked in carbolized oil, and afterward covered with a film of stearin. A limited trial of them leads me to think that they will prove efficient.

To secure drainage, I most often employ tubes of India-rubber, as recommended by Lister, and find it advantageous to insert tubes of large caliber, being careful to remove them as soon as practicable. As a rule, especially in deep wounds, free drainage is doubtless indispensable. But it may be expedient, in certain cases, to close the wound completely, provided it is aseptic. Thus, I have several times tied such arteries as the common carotid, the femoral, and the lingual; and, without using a drainage tube, have obtained complete primary union under a single dressing.

During the past year I have treated six compound fractures of the leg, and one compound fracture of the thigh, merely by thorough syringing of the wound with a five-per-cent. solution of carbolic acid, and then applying an iodoform dressing. All these patients recovered without suppuration.

Finally, I disturb operation wounds as little as possible, using infrequent dressings, and avoiding injections, unless there is evidence of putrefaction or copious suppuration.

3. *Results.*—Alluding only to my own experience, I can testify to a wonderful improvement wrought in the management of wounds by antiseptic surgery. Much study and practice are required to follow even its simplest methods; but, when these are faithfully observed, the results are most gratifying. Primary union is now the rule where formerly it was the exception; diffuse inflammation and suppuration are rare, even after severe injuries; operations once formidable now excite little apprehension; and that dreadful scourge, pyæmia, has been nearly abolished. In the surgical service of the Roosevelt Hospital, containing seventy-five beds, no operation performed during the last three years has been followed by septicæmia or pyæmia.

These results are surely surprising, and need hardly any comment. Many years ago it was the fashion to decry the microscope; but the condemnation came only from those who had never learned to use the instrument. In a similar manner, much of the opposition to antiseptic surgery at the present day springs from ignorance and prejudice, while those who have applied its principles most carefully have obtained the largest measure of success, and unite in acknowledging its achievements. It would be unwise to deny that further improvement in the treatment of wounds is possible, but it may be safely affirmed that, until something better shall be discovered, antiseptic methods will continue to prevail, and also that the methods of our predecessors are not likely to be revived.

REMARKS ON CARBOLIC-ACID, IODOFORM, AND CORROSIVE-SUBLIMATE DRESSINGS FOR WOUNDS.

By ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK AND BELLEVUE HOSPITALS.

It is no longer an open question concerning the germ theory in connection with the treatment of wounds. The principal point now is, What is the best method of either preventing or arresting the development of these germs? Up to quite a recent period, surgeons strictly following Lister, as was just, employed carbolic acid for this purpose, and the use of this arrestor of bacteric life became well nigh universal, and it is not yet deposed from its well-earned pre-eminence. An individual experience since 1877 in the wards at the Roosevelt, New York, and Bellevue Hospitals has taught me to lean in the main securely on this germicide. Yet it has, as all germicides so far known have, the disadvantage of occasionally acting toxically on patients. Within the past year I have had to record a speedy death which was due to carbolic-acid poisoning, after an operation for the removal of a tumor. Two other narrow escapes have

also brought me to listen to the claims of other antiseptics, coincident with the desire to simplify the somewhat complicated details of a full Lister dressing. A number of such new antiseptics have been of late brought to my notice. The two most important are iodoform and the bichloride of mercury (corrosive sublimate). It is not intended to give at length the records of the experience with these germicides, but merely to indicate some points connected with each that have been evolved by working with them. Iodoform has practically been in use in wound dressings since 1880, and its virtues as a powerful antiseptic have been generally acknowledged, but, in consequence of the number of mishaps that have occurred in the hands of various surgeons, a diminished freedom in its use has recently occurred, so that now, instead of using, as Mosetig-Moorhof and Mikulicz advised, from 10 to 20 grammes of the powder over a wound, incrusting to a depth of 1 to 2 millimetres, the caution comes from Neuber himself that an amount beyond 3 grammes (about 45 grains) can not be exceeded with safety when used on the surface of a wound. Under the use of iodoform I lost by death last winter, after a clitoridectomy, a young patient with the cerebral symptoms peculiar to poisoning by this drug; and, later, recognizing the cause in an amputation at the knee joint, followed by delirium, rapid pulse, etc., without other cause, removed the dangerous dressing and restored the patient. Such accidents have been met with by other surgeons, though the percentage is small compared with the total number of cases treated. Küster,* of Berlin, has encountered toxicæmic symptoms even after its employment in minute doses, and he says that under its use erysipelas and phlegmonous inflammations have appeared, which, under the Listerian treatment, have been of the greatest rarity. So many accidents occurred in his ward that a return was made to the carbolic acid. In the "Lancet" for October 7, 1882, it is editorially remarked, in connection with the subject of surgery in Germany, that "Germany seems to have taken up with zeal the question of a substitute for carbolic acid, and proposals have from time to time been made as to the use of salicylic acid, thymol, eucalyptus oil, and, more recently, of naphthalin and a preparation of common turf. Iodoform was supposed to have solved the difficulty; but, despite its value in healing wounds, it occasioned such derangements in the system generally that it fell into disfavor."

The difficulty of readily recognizing the symptoms of a poisonous dose of carbolic acid or of iodoform led to experiments early in the spring of the year at the New York Hospital with a new antiseptic. This was corrosive sublimate, the effects of which are quickly detected if acting poisonously, and the essay was based upon the trial tests made of various germicides by M. de la Croix,† an excerpt from which was published in the "Lancet" for March 4, 1882.

* "Centralblatt f. Chirurgie," 1882.

† The list is as follows: 1 gr. to 35 permanganate of potassium.

1 " " 478 acetate of aluminium.

1 " " 343 salicylic acid.

1 " " 410 iodine.

1 " " 431 chlorine.

1 " " 10 phenol.

1 " " 2,525 corrosive sublimate.

This experimenter undertook a series of trials with a number of antiseptics, with the result that 1 gramme of corrosive sublimate to 2,525 grammes of water was superior to all in killing bacteria, showing it thus to be the most potent of all. My results with it in three compound fractures of the thigh and six of the leg were very encouraging, and, on my return from my vacation, this treatment was resumed; and the result, so far, confirms a recent report on the subject by Kümmel, of Hamburg, at the last congress of the German surgeons,* giving a large and satisfactory showing concerning the value of this dressing. In over two hundred cases treated successfully by this method, Kümmel and Schede have met with but two slight cases of salivation.

The foregoing remarks have been made as a preface to the practical portion of detailing the writer's present mode of dressing wounds. First of all, it must be said that the carbolic dressing is considered by far the most reliable one; it has sundry inconveniences, some of which have been overcome, but many will continue to exist, due to the volatility of the antiseptic used.

In all incised wounds, or those whose depths can be readily reached by irrigation, the spray is omitted;† but this only takes place at the first dressing; all changes in the dressing, if an aseptic condition is maintained, are made under the protection of a spray,‡ as it is felt that the irregularities or infractuosities of a partially healed wound are not to be easily protected or cleaned out by irrigation. All forcible injection of a closed wound through drainage tubes is carefully avoided. It is in this way that carbolic-acid poisoning is often brought about; hence, to assure one's self of the patency of the tubes, it is only necessary to pass a probe through them.

Another deviation from the ordinary programme is the employment of Mr. Lister's latest *carbolicized*, *chromicized*, and *sulphuricized* catgut.* This gut can be kept dry in the pocket-case, like an ordinary ligature, and needs only to be immersed in the carbolic solution, 1 to 20, for a quarter of an hour prior to an operation. It is stronger than the old catgut, does not slip in tying, as does that kept in oil, and it does not so quickly dissolve or soften in the tissues. From personal observation I can state that it will remain *in situ* from eight to twenty-two days. Two simplifications are so far made. A third is the use of Bruns's|| formula in making the gauze. One can keep on hand, in private practice, a quart or so of this solution, and when it is wanted, the gauze, or whatever absorbing material is employed, can be wetted with it

* "Centralblatt f. Chirurgie," July 22, 1882.

† In laparotomy, kelotomy, oostomy, and in operations on the joints, the spray is always used.

‡ In Halle and Vienna, much irrigation and little spray are used; in Berlin and Kiel, much spray and much irrigation; in Munich, much spray and little irrigation; in Paris, spray and irrigation; in London, spray and irrigation.

§ The formula ("Lancet," May 1, 1882, p. 419) is as follows: Steep the catgut in a concentrated solution of chromic acid twelve hours, then in sulphurous acid (Br. P.) twelve hours, securing the ends to prevent untwisting. Sulphurous acid of only half the strength has lately proved to be better, leaving the gut as soft as before.

|| Bruns gives the formula by which a very soft, compressible, sterile gauze is made as follows: Resin, 400 grammes; salicylic acid, 100 grammes; castor-oil, 800 grammes; alcohol, 1 litre.

and immediately placed on the wound, or it can be kept for some time by being enveloped, *without any drying*, in a rubber cloth.* The other familiar details of the Lister treatment are still resorted to, viz., the "protective," the drainage tube of red or black rubber, the carbolized silk for sutures (not always previously waxed, but simply immersed in the stronger carbolic solution), and the Mackintosh. A retrograde step, so far as simplification is concerned, made to avoid the renewal of drainage tubes, which is usually done on the fourth to the sixth day, is the substitution of decalcified chicken-bone tubes, as suggested by Neuber for the ordinary rubber ones; with these, in a case otherwise progressing satisfactorily, the dressing is not renewed until soiled, or the parts healed. In using iodoform, the wound is irrigated frequently with a 1-to-20 solution of carbolic acid before the powder is lightly dusted or blown on by an insufflator, but no spray is used. All instruments and sponges are, however, protected by the customary carbolic solutions. The wound is then closed by metallic or carbolized silk sutures, drainage tubes of either rubber or bone are introduced, and a small pad or cushion of iodoformized gauze, or other absorbent substance, is then placed next the wound, and over this a larger mass of absorbent material, without any Mackintosh or other impermeable material over it, is applied, and secured by a lightly compressing bandage. Now, this omission of the outer impermeable layer may strike a devoted adherent of carbolic acid as a mistake, but the slightly volatile nature of iodoform permits the use of the undiluted antiseptic directly in contact with the wound, which is, it is said, thus protected very strongly from the secretions that may be tainted at the surface of the dressing. It is, moreover, found that less risk of poisonous action takes place if no Mackintosh or other impermeable substance is employed, and also if much pressure of the retaining bandages be not resorted to.

Of the materials utilized to soak up the discharges from the wound, there are three that are in common use besides the ordinary carbolized gauze. The first is the iodoformized gauze, which is prepared either by simply dusting a given quantity on several thicknesses of gauze, or, preferably, by the costly method of impregnating the gauze, previously washed, with 50 parts iodoform, 250 parts ether, and 750 parts alcohol; this gives a 10-per-cent. gauze. Bruns uses a solution of 1 part iodoform, 4 parts of resin, and 20 parts of alcohol. The gauze is wetted with this solution, and subsequently from 30 to 50 per cent. of iodoform is dusted on the sticky gauze, to which it adheres. Lately a new wound dressing has been introduced from the celebrated clinic of Kiel by Esmarch and Neuber, which possesses absorbability to a remarkable degree. It is peat- or turf-mold, very friable, light, and spongy. This, impregnated with 2½ per cent. of iodoform, is packed lightly in a small gauze bag, which has been previously disinfected with a

carbolic-acid solution; over this a larger bag, filled with plain turf, but saturated with a 1-to-20 solution of carbolic acid, is placed and secured with a bandage, considerably more pressure being resorted to than when gauze is used. Bags of sawdust are also used; impregnated with iodoform or corrosive sublimate and carbolic acid. Such dressings, with the decalcified bone drains,* often permit an amputation wound to be completely healed without any change. When such a prolongation of the dressing is intended, the outer bandage is stiffened by water-glass. Although sand, cinders, spun glass, and other substances have been suggested, the direction of trials in the New York Hospital has been toward perfecting the readily obtained and cheap sawdust dressing, and so far it has answered well. But nothing yet, it is true, has been found to surpass the effectiveness of the peat dressing, and, although it may in the future be obtained here, yet that employed now has to be procured by importation, and is hence expensive.

In the employment of corrosive sublimate as an antiseptic, a spray of one part to one thousand of water (about 8 grs. to the pint) is used, or a solution of a similar strength is irrigated over the wound, and at first gauze bags of turf or sawdust, impregnated with a like solution and dried, were used, but recently microscopic examinations have showed that they were of insufficient strength, and hence the absorbing dressings have been immersed in the stronger solutions which the larger experience of Kümmel has shown to be most effective—viz., 40 grs. of corrosive sublimate to the pint of alcohol, to which 5 jss. of glycerin is added. The sponges and compresses are kept in one-tenth-of-one-per-cent. solution, i. e., 8 grs. to the pint of water. The silk sutures are prepared by soaking for two hours in a one-per-cent. solution, i. e., 76 grs. to the pint, and subsequently kept in soak in the weak solution (one-tenth of one per cent.). The sublimate catgut is very strong and supple, and is made by placing it in the one-per-cent. solution (alcoholic) for twelve hours, and then in one-quarter-of-one-per-cent. (20 grs.—Oj) solution, to which is added 3 j of glycerin. Under such dressings, within the past ten days, an amputation at the hip joint has passed satisfactorily toward complete recovery.

Additional advantages of the sublimate dressing are its freedom from odor, its slight effect upon the hands, much less than from carbolic acid, and its cheapness and ease of preparation. For the disinfection of instruments, however, the carbolic-acid solution has still to be used, as the prolonged mercurial immersion is apt to dull cutting edges. With these three antiseptics all wounds under my charge are now treated, preference being given to carbolic acid. Next in order is the corrosive sublimate, iodoform being reserved for small wounds or injuries, such as crushed fingers, stabs, etc., or wounds involving the orifices of the body.

The statement that the antiseptic treatment is nothing but cleanliness, notwithstanding the remarkable cases of Tait, is not borne out by the experience of the majority

* This gauze is stronger than that of Lister, but it loses the carbolic acid more rapidly. This observation ("N. Y. Med. Jour.," Jan., 1880) has been confirmed by Kopff, who found that, on the second day after each kind was prepared, the gauze of Bruns contained 5.62 per cent. of acid, while Lister's only retained 2.61 per cent. In the ordinary gauze sold at the shops only one half of one per cent. was found.

* Experiments are now being carried out to determine if temporary drains can not be made of compounds of gelatin, and also of the chromicized carotid and iliac arteries of the sheep.

of the leading surgeons abroad. Volkmann reiterates his remark that no suppuration will take place if septic infection is prevented, and Esamarch and Nussbaum pronounce a surgeon criminal in neglecting antiseptic measures.

The tendency in the striving after new methods of securing this end, and in simplifying the more complicated dressings, is to neglect the thorough and complete first disinfection of a wound. It is better to err on the side of too much care than to assume that the antiseptic used has so much potency that no care at all need be taken. Since the satisfactory working of iodoform, for instance, I have seen surgeons ignore the care of the hands, sponges, and instruments—drying the wounds with towels after washing the same with carbolic solutions, etc. Whatever may be the theory, if an antiseptic is used it should be applied from the beginning of a wound, and kept applied until the wound has either healed or been placed beyond the reach of danger, by full granulation.

ANTISEPTIC SURGERY.

By J. WILLISTON WRIGHT, M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

If the question were asked me, whether I believed in antiseptic surgery or not, I should answer both *yes* and *no*.

Yes, if by antiseptic surgery is implied the thorough cleansing and disinfection of the hands of the surgeon and his assistants, together with his instruments and sponges, when about to perform an operation or dress a wound.

Yes, if by the term is implied the removal from the vicinity of an open wound or sore of all materials which are liable to infect it, such as decomposed serum, blood-pus, or particles of dead tissue; the removal, at the earliest possible moment, not only from the patient's person, but also from his room, of all soiled bandages, poultices, or other dressings, and the thorough cleansing of the injured part immediately thereafter with water impregnated with some one of the many so-called germicides or antiseptics, of which carbolic acid is perhaps as good as any, on account of its well-known property of preventing and arresting fermentation and putrefaction, on account of its cheapness, and the facility of obtaining it almost everywhere.

Yes, if the term embodies the purifying of the air of the patient's apartment, as far as possible, of such elements as are supposed to develop septicæmia, pyæmia, or erysipelas, whether in the form of living microscopical organisms, according to the theories of Pasteur, or in the form of minute particles of septic matter thrown off from the skin, from the lungs, or from the surface of the wound itself.

Yes, if it means the timely evacuation of all pent-up fluids, whether pus or other inflammatory products, and the making of suitable provision for their discharge as fast as formed, and before decomposition has had time to occur, by the use of counter-openings, position of the part, and the proper employment of drainage tubes.

Yes, if it means, in a word, perfect cleanliness not only of the wound, but of everything which comes in contact

with it, including fingers, instruments, sponges, dressings; including the patient's clothes and his bed linen, and including, last but not least, as perfect disinfection of the air of the apartment as can be secured, first, by thorough ventilation, and, secondly, by keeping the air more or less charged with carbolic acid or some other reliable antiseptic.

No, if it means that all wounds must necessarily do badly; that septicæmia, pyæmia, and erysipelas must be the rule and not the exception, without recourse to all of the endless details of Lister's method.

No, if it implies that the science and art of surgery have reached that state of perfection which enables their votaries not only to predict with absolute certainty the results of a given operation, but even to guarantee a successful termination.

No, if it would force upon us the doctrine that all wounds, whether of an incised, a lacerated, or a contused nature, do best when hermetically sealed under seven or eight layers of antiseptic gauze, with one or two of caoutchouc or oil silk coated with varnish interspersed.

No, if it would compel us to discard in all cases the open treatment of Humphrey and the water dressings of Sir William Fergusson as relics of a barbarous age, to be condemned, shunned, and avoided by all decent society, and especially by all surgeons who make the slightest pretensions to scientific attainment.

No, if it would have us believe that the statistical records bearing upon this question have always been fairly, honestly, or impartially made; or that when we are regaled with an array of twenty or more cases of amputation of cancerous breasts, for example, in the experience of one man, all done with strict attention to the details of Lister's method, and all resulting in union of the wound by the first intention throughout, there is not some part of the history of these or other cases in the experience of the same individual which, for reasons best known to himself, has not been told.

No, if it would have us believe that the better results which are now obtained in the treatment of surgical injuries generally, over those of even a few years ago, are attributable exclusively to the minutie of Lister's method; that no credit is due to the general recognition on the part of surgeons of the necessity for free drainage, the improved state of hospital hygiene, the importance of abundant air-supply, the avoidance of overcrowding, etc.

With regard to carbolic acid considered merely in the light of a dressing calculated to promote the cicatrization of wounds, and independently of its antiseptic properties, I believe that it acts as a stimulant to the parts to which it may be applied; that, like many other allied substances, it protects a sore from the air, bacteria, and contracts its surface, thereby lessening its secretion, and so favors those processes of nature whereby alone perfect repair can take place. But that its virtues in this respect are specially greater than those of alcohol, creosote, and many of the tannin-infusions, or that they are at all comparable with those of Peruvian balsam, for example, I have never had serious doubts.

The danger of poisoning by carbolic acid in the treat-

ment of open wounds, especially where considerable quantities are used, as in the syringing out of the cavity of a large abscess, are not so trifling, nor are cases of this kind so rare, as many of its warmer advocates would have us believe. For which reason, as also on account of its well-known irritating qualities, I do not think it is a proper substance to introduce into the peritoneal or pleural cavities in the form of vapor, as commonly used during operations, or in the form of a watery solution for washing out these cavities, except in a very high state of dilution.

Like other novelties in medicine and surgery which present themselves from time to time, carbolic acid has been the popular craze for the last fifteen years; it has been used externally or internally, in some form or other, for almost every ill that flesh is heir to.

That it has been the means, either directly or indirectly, of saving many lives, chiefly through the teachings of Professor Lister and his followers, no one who has been at all observant can deny; that it has killed a considerable number of people is equally certain; that it will not cure everything, and that it will not always prevent blood poisoning where the constitution of the patient is depraved and the blood vitiated, is a proposition too self-evident to require an argument for its demonstration.

That the majority of simple wounds occurring in a healthy subject, and treated under favorable local conditions, will heal equally well without it, is perhaps not so easy to prove, yet is generally acknowledged by a large number of careful, conscientious surgeons.

In a word, carbolic acid, considered as a panacea, has had its day; like bromide of potassium, like chloral hydrate, and many other new drugs, after having turned the heads of more than half of the medical world for a few brief years, it has, in this country at least, like them, come to occupy a definite place in the minds of the majority of physicians, or has come to be valued by them for just about what it is really worth, neither more nor less.

ANTISEPTICS IN EVERY-DAY PRACTICE.

By WILLIAM T. BULL, M. D.,

SURGEON TO ST. LUKE'S AND THE CHAMBERS STREET HOSPITALS.

WHILE the antiseptic treatment of wounds, either by Lister's dressing or some of its substitutes or modifications, is now carried out in most of our hospitals, it does not seem to be so generally adopted by practitioners as is desirable. It is admitted to be indispensable for all important operations and wounds, and in wards where many patients are aggregated, but is thought unnecessary, or of less value, in the minor wounds which occur in every-day practice. Or, if its advantages are not denied, it is thought to be too complicated, and to be too tedious to warrant its adoption.

Now, it is a fact that these minor wounds may be the starting-points of the most serious inflammations, and it is hence most important so to treat them as to prevent such inflammations. This can be most surely accomplished by carrying out strict antiseptic measures; and it is fortunately

the case that treatment by these measures has been much simplified in the past five years, so that no one can reasonably refrain from practicing it on the score of complexity.

Before mentioning in detail the class of cases to which I refer, let me point out the ways in which the original Lister dressing may be modified and made to answer all purposes for small wounds. In place of the expensive carbolyzed gauze, one may use the iodoform gauze* (made by rubbing the crystals into the meshes of well-washed cheesecloth), or compresses of lint or gauze wet in two-and-a-half-per-cent. solution of carbolic acid. Carbolyzed catgut may be replaced by silk which has been boiled for an hour in five-per-cent. solution of carbolic acid, and kept in that solution. This will serve both for ligatures and sutures, but is not so sure to prove unirritating as catgut. The "protective" may be dispensed with, and the spray is not needed, since one can rely on irrigation with a five-per-cent. solution. But the utmost care should be taken to cleanse the parts about the wound, the hands of the surgeon, and the instruments, using for this purpose the five-per-cent. solution of carbolic acid.

Among the cases that fall frequently under the exclusive care of the general practitioner, and in which surgeons are not consulted, are scalp wounds, wounds of the hand, and small wounds in the vicinity of the larger joints, or overlying the pleural or peritoneal cavity. Even the most trifling of these wounds may have serious consequences. From scalp wounds erysipelas is a frequent and pyæmia an occasional result, while finger and hand wounds are frequently attended with prolonged suppuration in the sheaths of the tendons and the cellular tissue of the forearm; and synovitis, pleurisy, and peritonitis often follow superficial wounds. It is needless to dwell on the importance of these wounds. It is sufficient to say that their ill consequences may be avoided by preventing sepsis during their healing.

In all scalp wounds the head should be thoroughly washed with the five-per-cent. solution, and, in all but the smallest, the hair cut off about the wound. After stopping bleeding with the ligature, or, better, by the application of forcipressure forceps for a few minutes, the wound itself should be irrigated with the same solution. Small incised wounds of the scalp alone (without gaping) require no sutures; only a pad of iodoform lint on either side, and a third larger pad to cover and extend beyond them, held in place by a snug bandage. Larger wounds, with detachment of the scalp, or exposing the bone, may be sutured, but must be carefully drained with horse-hair (previously cleansed with ether and five-per-cent. carbolic-acid solution) at the ends of the wound, and through a counter-opening at the most dependent point, and covered with iodoform gauze (or compresses of lint wet in two-and-a-half-per-cent. solution), overlapped by gutta-percha tissue. Finally, wounds with much contusion, or laceration, or loss of substance—in general, those in which healing by granulation is the best that can be hoped for—will do best if stuffed with iodoform gauze, or the lint wet in two-and-a-half-per-cent. solution, and covered with absorbent cotton and gutta-percha tissue. The iodoform dressing should be renewed when discharge appears

* Seabury & Johnson, who manufacture a superior carbolyzed gauze, promise to furnish soon an equally satisfactory iodoform gauze

on its surface or at its edge; the compresses of two-and-a-half-per-cent. solution twice or three times in twenty-four hours. (A Lister dressing will need changing only after intervals of several days.) If decomposition should occur, the wound must be irrigated with five-per-cent. solution. But, if it remain sweet, it must not be disturbed (washing, etc.), except to renew the dressing.

Wounds of the fingers and hand require most careful cleansing, both of the wound and the parts adjacent, with five-per-cent. solution, since they are mostly complicated with foreign matters, such as dirt, machine-oil, powder, glass, etc. For small incised wounds, neither drains nor sutures are necessary. Careful approximation of the edges by compresses with strips of iodoform gauze (applied like adhesive plaster), covered by cotton and rubber, will suffice to secure first intention. Deeper incised wounds should have a horse-hair or rubber drain, and cut ends of tendons be sutured with carbolized silk cut short. All lacerated and contused wounds, including compound fractures and dislocations with detachment of the skin, should be left to granulate, and no parts removed by operation which are not actually dead. (I am satisfied, from the experience of many cases at the Chambers Street Hospital, that this is the best course to follow. I have often been disappointed in the effort to unite and drain this class of wounds, with a careful Lister dressing too, and had cellulitis follow. On the other hand, the most serious lacerations have, when left open, granulated finely in from five to ten days, without the least local or constitutional reaction, and with moderate and sweet suppuration.) After the irrigation, all recesses of the wound, especially those beneath detached skin and fascia, should be lightly stuffed with iodoform gauze, and the cotton and gutta-percha outside dressing applied to the entire hand and wrist with a splint. In place of the iodoform gauze, the compresses of two-and-a-half-per-cent. solution of carbolic acid may be used; but this is not so sure to preserve asepsis, and will need to be renewed every day, if covered with gutta-percha, or kept constantly wet with the same solution. After the wound granulates, useless parts should be amputated, and cicatrization promoted by skin grafting and strapping with adhesive plaster. The most rapid growth of the cicatrix I have found to follow the boracic-acid dressing. The surface and edges are protected with gutta-percha tissue, oil-silk, or (best of all) "protective" wet in five-per-cent. solution of carbolic acid. Over this, and projecting an inch or more beyond, comes a compress of lint wet in a saturated solution of boracic acid, and then an elastic bandage, which must be very evenly and smoothly applied. This will require renewal only every third or fourth day. It is more suited to ulcers of the arm and leg, however, where, without exaggeration, I have seen the cicatricial edge advance fully an inch from all sides under one dressing.

In the third class of cases that I have referred to—that of small wounds overlying the greater joints, or the thoracic or abdominal cavity—the greatest care is needed to prevent sepsis. After thorough washing, the discharge should be given free vent through the largest drain the wound will permit (a counter-opening is often advisable), and iodoform gauze, or the carbolized (two-and-a-half-per-cent.) com-

presses, applied as above described. If one were in doubt whether the cavity was opened or not, it would be best to apply the five-per-cent. solution on a sponge, or (better) to spread a thin film of iodoform on the raw surface. At all events, the wound had better not be tightly sutured; and, on the first appearance of inflammatory reaction, it should be opened, irrigated, stuffed, and left to granulate under a dressing. In cases of slight punctured wounds, such as are made by sharp hooks, or pocket-knives, it might be safe to dispense with drainage, especially if the wound had been but a short time exposed to the air, and there was no reason to fear the presence of foreign matters; but, in general, I should feel safer from septic influences with a freer wound thoroughly carbolized, or iodoformized, and drained, than with a small one left to Nature's sealing process, that of the coagulation of the blood in it. Of course, absolute rest should be enjoined. The following case illustrates the sad result of neglecting this class of wounds: A laborer was brought to the Chambers Street Hospital suffering from suppurative synovitis of one knee joint. A week before he was stabbed over the knee with a pocket-knife, and walked to a doctor's office. A piece of adhesive plaster was applied to the cut; he was told that it amounted to nothing, but recommended to keep quiet. The joint began to swell, but he delayed seeking advice till high fever came on. On admission to the hospital the joint was full of pus, he had pneumonia, pericarditis developed a day or two later, and the autopsy, ten days after the injury, revealed pyæmia.

A word of caution as to the infection of wounds by the practitioner himself may be *apropos*. We all know that it is possible to carry the germs of puerperal septicæmia from one woman to another; and it is equally possible to carry germs from a septic wound to a healthy one, and to set up unhealthy action in the latter. It is advisable never to go direct from an erysipelatous patient to one with a healthy wound, and one should never pass from the dressing of one wound to another without elaborate cleansing of the hands with five-per-cent. solution. The following is a good instance of infection through the surgeon, which came under my notice recently: A dispensary surgeon dressed a hand with severe cellulitis, and a half hour later, without washing his hands, sewed up a slight wound in the cheek of a healthy child, and applied a cold-water dressing. Twenty-four hours later the child was brought back with vomiting, high fever, and erysipelas of the face. Careful inquiry failed to find any source of infection in his surroundings.

Such dressings as I have described can not be reasonably called complicated. The materials are easily procured, they are easily applied, and without the sacrifice of much time. In the end, from the infrequency of their renewal, and the more rapid course of the healing process, much time is saved to both physician and patient. It is in the power of the physician, by the use of these antiseptic measures, to secure a prompt and inoffensive healing of such wounds as I have mentioned, and to avoid all secondary inflammations. I do not mean to assert that he will be successful in every case. Neglect on the part of the patient, disarrangement of the dressing, or its failure to prevent sepsis, may cause an occasional bad result, but these

are conditions beyond his control. But my own experience tells me that if he takes every precaution he will secure the best result in the great majority of cases.

2 EAST THIRTY-THIRD STREET.

CASE OF OSTEOMA OF THE CONJUNCTIVA.

By E. G. LORING, M. D., NEW YORK.

The patient was a healthy and well-developed child of eight months. Just after its birth, a small fold of "skin," as the mother said, was noticed in the upper and outer angle of the eye. This fold began to be more and more apparent until the child was five months old, when it attained its present position and size, which have not changed during the last three months. The eye has never been at all red except to a trifling degree, and then only at times over the fleshy protuberance. Nor has there been any pain connected with it. The protuberance presented the appearance of a small oval cystic growth, midway between the outer angle of the eye and the edge of the cornea, and was in about the horizontal meridian. It was not until the forceps touched the mass after opening into the fold that its bony or cretaceous character was suspected. It was firmly attached to the conjunctiva above and at the sides, though it did not appear to be attached at all to the globe. The operation healed kindly, there only remaining, at the end of the fourth week, when the child was last seen, a slight injection along the wound.

The other eye was perfectly normal. The child has a slight navel-looking spot on each upper lid.

The weight of the mass was 45 milligrammes; length, 8 mm.; width, 5.5 mm.; height, 2.5 mm. It was oval in shape, with the long diameter in the horizontal meridian of the eye. It was convex above and concave below where it rested upon the sclera.

The specimen was given to Dr. W. H. Welch, and his report is as follows: The bony growth is enveloped in a thin fibrous capsule. The growth is found to consist of true bone. Thin slices removed with the scalpel show perfectly formed lacunæ and canaliculi. No large medullary spaces are found, but there are Haversian canals, around which the bone corpuscles are arranged in lamellar systems. The addition of acid to a fragment of the specimen causes an evolution of abundant bubbles of gas, leaving behind an organic residue.

Dr. Welch reports that only two other cases which had been reported are known to him. These are found in Graefe and Saemisch's "Handbuch d. gesamt. Augenheilkunde," Bd. iv, Th. 2, p. 151, 1876. He finds no reference to any cases since then in Virchow and Hirsch's "Jahresbericht."

Dr. HUNTER MCGUIRE writes to the editor of the "Virginia Medical Monthly" concerning the title of "Emeritus Professor of Surgery in the Medical College of Virginia," erroneously appended to his name in the "International Encyclopedia of Surgery." He expresses his surprise and mortification at the mistake, stating that he resigned the chair of surgery in the college several years ago, and has since had no connection with the institution.

Correspondence.

LETTER FROM BOSTON.

Boston, November 13, 1882.

AMONG those matters likely to prove interesting in correspondence from another city, the subject of medical charities stands prominent. Of the older institutions of Boston, however, the Massachusetts General Hospital and the City Hospital, there is little to say that is not known to most of your readers. The former has recently opened its beautiful Convalescent Home at Belmont, a charming town a few miles from Boston, and everything is in good working order. A new building has been erected for the Training School for Nurses, and will soon be dedicated. The Out-patient building, which has long been overcrowded, is to have an additional story, so as to better accommodate the throat and skin departments; and, when these changes are finished, we may expect others. In fact, it is an open secret that another new ward will be begun in the spring, upon the remaining available space in the hospital grounds. Soon the trustees will begin the buildings for the lunatic department of the hospital, now called the McLean Asylum, which is at Somerville, situated upon a hill overlooking Boston. The base of this hill is surrounded by railroads; in fact, one railroad runs directly across the grounds. I say soon, for it is only a question of time, and that in the near future, when the land can be sold for enough to build a model asylum on the corporation's beautiful grounds near the Convalescent Home.

The Carney Hospital, carried on under the direction of the Catholic Sisters, is situated on the historic "Dorchester Heights," in South Boston, having a more beautiful and extended view than any like institution in Boston, overlooking as it does the harbor and the surrounding country. It is the only general hospital in our neighborhood where patients having private rooms can select their physicians from those who are not on the hospital staff. It is also the only one where ovariectomy is done under the hospital roof, Dr. John Homans having performed fifty of this class of operations there.

The Adams Nervine Asylum is situated in one of the outlying wards, near where we hope to have a park, when our city fathers can agree to accept the liberal offer from the Overseers of Harvard University, they offering the Bussey Arboretum to the use of the public if the city will build, and keep in repair, walks and drive-ways, and furnish police service, the care of the grounds being paid for by the college. Founded through the generosity of the man whose name it bears, the Nervine Asylum has, during the short time it has been open, demonstrated that there was a wide field of usefulness ready for it, and that it is doing its work well. As one of the trustees of the Adams, and also of the McLean, said to me, "I can not help thinking that by our work at the Nervine we are preventing people from going to Somerville, taking them in time to benefit them." Dr. Frank Page, formerly of the McLean Asylum, is the resident physician.

Some twelve years ago the Children's Hospital was organized upon a small scale. Now its sphere of usefulness has largely outgrown its present quarters, and it will soon be moved into the spacious new building on Huntington Avenue. The exterior is plain, without any attempt at ornamentation; but everything that sanitary engineering and plumbing can do has been done, and, though the location, on sanitary grounds, is not the very best, a brilliant future may be predicted for it.

One of the oldest and best-conducted of our charities, but one little heard of outside of the city, is the Boston Dispensary. For years before out-patient departments were thought of, the afflicted poor were treated in a quiet way at its building in Ben-

nett Street, and its district physicians went over the whole of it, not only giving advice and furnishing medicines, but in many cases providing food and raiment out of their own private means. In the directors' room in the Dispensary, over the fire-place, is a carving representing the biblical story of the Good Samaritan. In many houses the district physician has put that scene in practice. So quietly has the institution done its work that many charitable people have never heard of it. Recently it has made an appeal for money in order to erect a new building. The plans are drawn and have been accepted (not, however, till they had been examined and approved by the medical board), and soon work will be begun, and we shall have a model building, which will accommodate the staff and the greatly increased number of patients.

Another new building of interest to your readers is the new Harvard Medical School. Situated on Boylston Street, near a number of handsome churches and other public buildings, it is an ornament to the city, and one that all those interested in medical education may be proud of. It is the intention of the Faculty to have everything in readiness for the new year, and fitly celebrate the centennial year of the Medical School.

Dr. Oliver Wendell Holmes has resigned his professorship in the Medical School, as most of your readers are doubtless aware. For over a quarter of a century he was Professor of Anatomy and Physiology; but since these subjects were separated, upon the introduction of the "New System" of medical education, he has continued to show that the study of anatomy can be made anything but a dry subject. It will be hard to fill his place satisfactorily to all. Fortunately the funds in the hands of the Overseers for the Chair of Anatomy will be large enough to attract a capable anatomist, for, by combining the "Parkman" and "Wyman" professorships, about \$8,000 a year will be at their disposal. Of course, this would render occasional lectures at Cambridge necessary; but a man with that salary would be expected to devote his whole time to the subject. What the University loses by Professor Holmes's resignation the literary world at large will gain.

It is a common saying with us that any deserving charity can get all the money it asks for. One such institution has just received a handsome sum without asking for it. The Boston Lying-in Hospital has had a bequest of \$50,000, which will enable it to continue its good work without annually appealing for aid.

This hospital was an old corporation which apparently had outlived its usefulness; and for twenty years the only sign of life it gave was the annual meeting of the directors, who at such times voted various sums to certain charities. The principal in the mean time kept increasing, and in all probability would have continued to increase, without doing any good, to this present day, but for the energy of one of the younger men in the profession, who awoke the trustees to their duty, and had the new hospital opened. Now, though only in its tenth year under the new management, it is doing as much work as its present quarters will permit.

The Massachusetts Medical Benevolent Society held its twenty-fifth anniversary a short time ago, and celebrated it by a dinner at Young's Hotel. The event was a very enjoyable one. The object of the society is to give financial aid to widows and orphans of medical men. The funds amount to \$20,000, and each beneficiary receives \$80 a year.

These are the greater charities. To speak of the various special hospitals and day nurseries would be too much in a letter like this; hereafter I may refer to them in various connections.

F.

Book Notices.

The Treatment of Diseases by the Hypodermic Method. By ROBERTS BARTHOLOW, M. D., LL. D., Professor of Materia Medica and General Therapeutics in the Jefferson Medical College of Philadelphia. Fourth edition, revised and enlarged. Philadelphia: J. B. Lippincott & Co., 1882. Pp. 365. [Price, \$2.]

This edition of Professor Bartholow's well-known work is considerably larger than the third, and the author informs us that it has been in great part rewritten, all well-proved advances in our knowledge of the subject having been incorporated in it. As it stands, it is a most useful and instructive monograph, on a theme of the utmost practical importance.

Nitro-Glycerin as a Remedy for Anginal Pectoris. By WILLIAM McRELL, M. D., M. R. C. P., Lecturer on Materia Medica and Therapeutics at the Westminster Hospital, etc. Detroit: George S. Davis, 1882. Pp. 78. [Price, \$1.25.]

This is an exhaustive monograph on nitroglycerin in medicine; its preparation, administration, and effects. Special reference is made to its use in the treatment of *anginal pectoris*. The subject is very thoroughly discussed in all its aspects. Nitroglycerin being a new remedy, and so little having been written about it except in journals, the author's little work is an important addition to literature.

Keys to Rational Therapeutics. By J. MEYER FOTHERSILL, M. D., M. R. C. P. New York: G. P. Putnam's Sons, 1882. Pp. 121. [Students' Aids Series.—Price, 25c.]

This little work is written in exactly the same style as the author's larger *Hand-book of Therapeutics*. It needs no other description than the statement that it is a miniature of the larger book, differing from it merely as to the fullness with which the subjects are treated of.

BOOKS AND PAMPHLETS RECEIVED.

Anatomical Technology, as applied to the Domestic Cat: an Introduction to Human, Veterinary, and Comparative Anatomy. With Illustrations. By Burt G. Wilder, B. S., M. D., Professor of Physiology, Comparative Anatomy, and Zoology in Cornell University, etc., and Simon H. Gage, B. S., Assistant Professor of Physiology and Lecturer on Microscopical Technology in Cornell University, etc. New York and Chicago: A. S. Barnes & Co., 1882. Pp. xxvi+575. [Price, \$4.50.]

The Diseases of the Liver, with and without Jaundice; with the Special Application of Physiological Chemistry to their Diagnosis and Treatment. By George Harley, M. D., F. R. S., F. R. C. P., Physician to University College Hospital, London, etc. Illustrated by colored plates and wood engravings. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. 751. [Price, cloth, \$7; leather, \$8.]

The History of Cholera in India. A paper read before the Ohio State Medical Society, June 24, 1882. By D. S. KENNEDY, M. D., Columbus, Ohio.

Conjoint Session of North Carolina Board of Health and Medical Society of North Carolina, held in Concord, May 10, 1882.

Notes on Cases of Secondary Syphilis Cured by Electricity after all Other Methods of Treatment had Failed. By John BATH, M. D. (Hippocratic Society, "New York Medical Times") London Water Supply. Report, etc. No. xxi.

Walsh's Physicians' Combined Call-Book and Tablet, from 1880 to 1888. Second edition. Washington: H. B. Williams, M. D. Price, \$1.00.

MEDICAL TRAINING FOR NON-MEDICAL WORK.

For a man to forsake the practice of the law and devote himself to statecraft is of such common occurrence that a knowledge of the law has almost come to be looked upon as necessary to a creditable career on the part of a public official or a legislator. From the chancel to a professorship in some institution for the instruction of the young is a step to which we are little less accustomed. But let a physician find, after years spent in fitting himself for practice, that medicine is not to his liking—there seems to be no other vocation into which, more than into others, he is naturally and obviously led. It is true, artistic anatomy is commonly supposed to be among the acquirements with which a well-educated physician should be credited, and a knowledge and a love of this branch account, from the popular point of view, for the success which in many instances physicians have met with in painting and sculpture. In particular, we have lately had this idea held up as an explanation of the excellence of some of Mr. Seymour Haden's etchings, Mr. Haden being a surgeon, as many of our readers are doubtless aware. Now, apart from the fact that such men's best work is quite as often shown in other branches of the pictorial art as in their delineations of the human figure, if not more so, we have very decided doubts as to whether more than the most trifling aid is derived by them from such knowledge of human anatomy as they acquired in the medical curriculum. Moreover, painting and sculpture, although often taken up as a diversion, do not seem to be at the bottom of more defections from the ranks of medical practitioners than many another calling that might be named. They, therefore, form no exception to the general fact that there is no obvious way out from a career in the practice of medicine.

The field of investigation in the natural sciences has proved attractive to many who have renounced medical practice. A noteworthy example will be brought home to the minds of many of our readers by the recent untimely decease of Professor Henry Draper, whom medicine may well be proud of having added to the number of workers in pure science. The student of medicine is too apt to look upon the natural sciences only as subsidiary to medicine, but now and then the means proves more to his taste than the end, and he lingers in the by-way, forgetful of the high road he started for. In no wise should such a course be thought retrogressive, under the idea that we have alluded to, that the natural sciences are chiefly of importance as tributaries to medicine. Those sciences touch human progress and human happiness at many other points than those immediately connected with the matters of health and disease. Not for a moment would we gainsay the justness

with which medicine assumes to be in a certain sense the sum of the sciences, for to a great extent that assumption is well founded. It is a practical fact, however, that one may forsake the practice of medicine, and devote his life to the study of one or more of the physical sciences, without in the least lowering the high station which he originally proposed to himself to attain. Even were this not the case, it would by all means be desirable for a man to give up practical medicine, in favor of a more congenial pursuit, when he finds that success in medicine, far from being assured by the best attainable mastery of it as a science, demands also the ability to manage men, a capacity in which he may find himself sadly wanting.

Turning to literature, we shall find that none the more does that pursuit afford a refuge for those who wish to cut loose from the practice of medicine, for a fondness for literary work is prone to show itself, if ever, earlier in a man's life than the time at which he usually enters upon the study of medicine; therefore it may divert many from ever engaging in medical study, but can scarcely draw off many who have already gone through with the curriculum. This we say in spite of Professor Oliver Wendell Holmes's recent renunciation of his position as a teacher of anatomy, for the purpose of devoting his whole time to literature. His life-long prominence in the little knot of American writers of excellence would vitiate any contradiction that the instance might be taken as opposing to our statement, even if he had ever been a practitioner of medicine, and certainly that occupation has never formed any considerable part of his career.

Turn in whatever direction we may, then, we see no calling into which that of medicine naturally runs. And yet many find it the wiser part, to change their pursuit. We are inclined to think that this course will be exemplified more and more as the profession gets to be more and more over-crowded. No doubt the step would be taken oftener were it not for a certain repugnance to what has been called "pulling up and coming down"—a feeling that is natural enough, but by no means warranted by the facts. To change one's pursuit argues no sense of unworthiness so long as the change is not a descent, but rather gives proof of a creditable self-appreciation. Given a well-founded recognition of one's comparative unfitnes for the practice of medicine, the renunciation of that pursuit is praiseworthy and for the common good. Let it not be thought that we would counsel a discontented or unsuccessful practitioner to throw up the game on a mere whim, or for any but the most cogent reasons; success in medicine often comes late in life, and we would advise no one to take such a step without having first convinced himself that he is positively unfitted for a medical career, and that he has a real aptitude for some other calling equally honorable.

THE NEW PHARMACOPŒIA.

I.

THE sixth decennial edition of the Pharmacopœia of the United States, recently published, deserves more attention than is ordinarily accorded to works of its class. On that account

urinary surgery; gynecology and obstetrics are in the hands of Dr. Paul F. Mundé and Dr. W. Gill Wylie; Dr. Emil Gruening and Dr. David Webster have charge of ophthalmology; and Dr. V. P. Gibney takes the orthopædic branch of surgery, with Dr. Charles F. Stillman as adjunct. Besides these well-known gentlemen, there is a corps of twenty-three assistants, also made up of excellent material.

It is undoubtedly the case that practitioners from various parts of the country come to New York in yearly increasing numbers for the purposes of recalling their half-forgotten lore in a pleasant and expeditious way, of studying disease more systematically than the opportunities afforded by private practice readily admit of, and of sharpening their practical acumen by closer contact with others engaged in the same pursuit than can fall to their lot in sparsely peopled districts. To such men the older colleges have attractions of their own, and it is scarcely to be supposed that these attractions will be at all dimmed by the younger institutions; but, quite apart from the pabulum afforded by the former, there can be little question but that the Post-Graduate School and the Polyclinic will offer supplementary advantages that will be availed of by great numbers. Nor is it necessarily to be expected that there will be any hard and fast choice between the two; the men of whom we speak come with a settled purpose to make the most of all opportunities they can find, and they will not be slow to recognize the wisdom of attending both institutions. There is, indeed, no incongruity in such a course, and we heartily trust that both schools may draw largely from the same body of pupils.

THE NEW INFECTIOUS DISEASES ORDINANCE OF BALTIMORE.

In a supplementary sheet published with the December number of the "Medical Chronicle," of Baltimore, we find the full text of a new ordinance now in force in that city in regard to the duties of physicians and others in the matter of such infectious diseases as small-pox, cholera, yellow fever, malignant diphtheria, and scarlet fever. By this ordinance the Commissioner of Health is vested with powers that would seem to be quite adequate to any possible emergency affecting the health of the city—powers so plenary, indeed, as to carry with them the gravest responsibility, and to call for the utmost discretion in the selection of that functionary. Concerning many of its sections, to be sure, it may be said of the ordinance that it requires the concurrence of the Mayor in the Commissioner's acts in order to make them valid, but it goes without saying that a Commissioner at all worthy of the place must feel that on his own shoulders rests the real responsibility. In view of this state of things, it is to be hoped that the office can not fall to a non-medical man.

Physicians are required to report all cases of the diseases mentioned within twenty-four hours after their first visit, and a like requirement is made of all keepers of hotels or boarding-houses, and indeed of householders in general, as well as of officers and consignees of vessels in port. Reports of deaths

from these diseases, too, must be made within twenty-four hours, with a statement of "the specific name and type" of the disease. It occurs to us in this connection that the term "malignant," as applied to cases of diphtheria, opens a loop-hole for evasion, since a difference of opinion may be maintained as to the precise applicability of the term in individual instances. It seems to us that, if diphtheria is to be reported at all, the requirement should extend to all cases.

There is a stringent section forbidding the landing or near approach to any wharf or building of any infected skins, fish, rags, bones, hides, or like articles, or their storage within the city, without a written permit from the Commissioner; also the sale, exchange, or exposure of infected straw, bedding, clothing, or other articles, until they have been adequately cleansed or disinfected. A prohibition to the same purpose attaches to the exposure of individuals to infection by allowing them to inspect houses where infectious diseases have occurred, with a view to buying or renting; and a particularly explicit section forbids the use of any public vehicle for the transportation of any person affected with any of the diseases mentioned; or of the body of any person dead of such disease—unless it can be shown to the Commissioner's satisfaction that such vehicle is used for those purposes only—on pain of the seizure and detention of the vehicle for the purpose of its disinfection.

The Commissioner is also given power to order the evacuation of any over-crowded or filthy habitation, visited with an infectious disease, whenever in his opinion such a course is demanded for the protection of its occupants or their neighbors, maintenance being afforded by the city to those who may thus be taken from their dwellings. For like reasons he may close streets and practically quarantine whole districts, setting sentinels to guard his muniments, and displaying a yellow flag in front of the infected premises.

Vaccination may be made compulsory in the case of any individual whenever the Commissioner considers it necessary, provided five years have elapsed since such person was last vaccinated. The penalty for violating any of these requirements is a fine ranging from one dollar to two hundred for each offence, but it is specified that the fine for refusing to be vaccinated shall not exceed ten dollars. The vaccination of all infants before attaining the age of one year is made compulsory upon parents and guardians.

We do not understand that this ordinance is temporary in its operation, and designed only to meet an emergency; it seems to be meant for permanent application. If this is the case, it must be called somewhat more sweeping than most communities are willing to submit to.

THE VISITING LISTS.

The physicians' pocket-books known by the name of visiting lists, or some term more or less equivalent, have come into very general use, and their leading characteristics are so well known that we need not enter upon any description of them. It is probable that most physicians who use them are accustomed to one or another, and are likely to continue with that particular one. In truth, there is very little choice between

them, as they all contain very much the same sort of printed matter, together with blank pages arranged for a simple form of book-keeping, memoranda of professional engagements, addresses, etc. Those that have reached us for the year 1882 are: 1. Lindsay & Blakiston's "Physician's Visiting List," now published by Messrs. P. Blakiston, Son & Co., of Philadelphia. This seems to be the oldest of them all, being now in the thirty-second year of its publication. 2. "The Physician's Hand-Book," prepared by Dr. William Elmer and Dr. Albert D. Elmer, and published by Mr. W. A. Townsend, of New York. This is rather a thick book for the pocket, owing mainly to the extended list of remedial agents contained in it. 3. "The Medical Record Visiting List, or Physicians' Diary," published by Messrs. William Wood & Co., of New York. This strikes us as more tastefully got up than the others, and as commendable for the brevity of its printed matter. 4. "Walsh's Physicians' Combined Call-Book and Tablet," published by Dr. Ralph Walsh, of Washington, who also publishes the "Physicians' Handy Ledger," concerning which we have before taken occasion to speak in terms of commendation. The "Call-Book and Tablet" is a fitting companion to the larger book, and both seem to be very handsomely arranged.

Proceedings of Societies.

NEW YORK MEDICAL AND SURGICAL SOCIETY.

A STATED meeting was held October 14, 1882. Dr. T. GARLAND THOMAS, President, in the chair.

PARALYSIS OF THE ARM FOLLOWING SLIGHT HANDLING OF THE MEDIAN NERVE.—About ten days ago Dr. ALFRED C. POST removed a tumor from the axilla of a gentleman some thirty-five years of age, who had first noticed the growth five or six weeks before. When Dr. Post saw it, it was between the size of a hen's egg and that of a goose's egg. It was not attended with pain, but was growing somewhat rapidly. On cutting through its investments, nearly to its substance, it appeared to be very closely adherent to the median nerve, so that it seemed likely that it was a neuroma, and that it might be necessary to excise the nerve; but, on cutting through the remaining investment, the tumor was enucleated without injury to the nerve. The nerve had been handled during the operation, but not rudely. To Dr. Post's surprise, he found, the next day, that there was paralysis of both motion and sensation of the forearm and hand, not absolutely complete, but nearly so. A year or two before, the patient had had a swelling about the shoulder, which was regarded as rheumatic; it continued a number of days, and at that time he had paralysis of the same parts. The nerve, therefore, had been weakened by previous pressure or disease. The patient was now gradually recovering from the paralysis.

NECROSIS OF THE LOWER JAW DUE TO A FRAGMENT OF TOOTH.—Dr. Post also narrated the following case: A sequestrum of the lower jaw, which he presented, was removed six or eight weeks ago from a young man who, about two years before, applied to a dentist to have a bicuspid tooth extracted. The tooth was broken, and the principal part of it was left behind; no immediate irritation followed, but, after the lapse of a year and a half, inflammatory swelling occurred over the bone, and portions of dead bone were discharged, together with the remnant of the tooth. For a long interval thereafter no fragments of bone were discharged. When the patient applied to Dr. Post there was a sinus leading to roughened bone. He cut down and removed the sequestrum shown. The special inter-

est of the case was with reference to etiology. The necrosis came on at a somewhat remote period after the extraction of the tooth, a part of which was left behind; then irritation increased until a considerable portion of the jaw had been lost.

Dr. HERBERT B. SANDS has found in some cases of comminution Dr. Post's a few months before. These cases have been connected with the case which produced the tumor and paralysis, but he is unable to explain it. A man entered Roosevelt Hospital on account of necrosis of the lower jaw. The inflammation which had led to necrosis followed the extraction of a tooth. On examining the patient, it was not discovered that anything remarkable had occurred during the performance of the operation, but he stated that soon afterward a severe inflammation followed, and when he presented himself for admission the bone was found dead and separated. The peculiarity of the case was that the necrosis was very extensive. It involved nearly one half of the jaw, extending down to within half an inch of the symphysis, and nearly to the level of the articular extremity. The necrosed portion was in many fragments—perhaps eight or ten—which were readily removed with the forceps. Dr. Sands was unable to explain why there should have been so many pieces of bone. There could not have been that amount of comminution at the time of the extraction of the tooth, he imagined, nor could fissures have taken place in so many directions. The man made a good recovery, and now looks well formed.

THE TREATMENT OF RUPTURE OF LARGE BLOOD VESSELS COMPLICATED WITH A SUBCUTANEOUS LESION.—Dr. SANDS would like to elicit the experience of the surgical members of the society in regard to the treatment of ruptured arteries and veins of large size with subcutaneous lesions. A lad, fifteen years of age, came under his notice on the preceding Wednesday evening, having received an injury at five o'clock on the morning of the same day from having the left thigh caught between two sail-boats. The boats came into collision with considerable force. The boy's leg was hanging over the side of one of the boats, and the thigh was caught between them, so that the force was applied laterally at about the lower third of the femur. Upon the outer and inner side of the limb there was well-marked ecchymosis, covering an area of several square inches. The boy said that within five minutes of the time of the injury the limb reached a large size, and at the time of his admission it was found very greatly swollen, the swelling extending up to the middle of the thigh, and involving the popliteal space. The swollen parts were exceedingly tense; the leg was cold, and, although not devoid of circulation, the passage of blood through the veins and capillaries was very sluggish. The pain had subsided when he entered the hospital, and, indeed, the leg was almost insensible. He had almost ceased to feel shock. No pulsation could be detected in the femoral artery at or below the seat of the injury. Dr. Sands had no doubt that it was a case of rupture of the artery or vein, or both; it was well known that, when an artery was ruptured completely, pulsation was generally absent. As to a murmur, some authorities stated that it was rare, and even that it was not. Where the rupture was partial the signs of traumatic aneurism—that is to say, pulsation, and a murmur—were usually abundantly observed. He proposed to cut down and remove the bleeding vessels, or, failing in that, to amputate the limb. But the boy's condition was so poor, and bleeding could be done but to wait. On Thursday the boy's condition was improved. He had passed urine, and the temperature of the limb had risen. It was thought that the arterial circulation had nearly disappeared, and the circulation was more active, the capillary circulation being quite so. The venous circulation still seemed to be gone. Mr. FRASER has just given a goodly number

delirium had occurred during the previous night, the temperature had risen to 103° F., the limb was cold, and gangrene was evidently threatened. Still there was capillary circulation in all parts of the limb. To-day, Saturday, his condition was not much changed. Perhaps there was a little more swelling, with a little extension of the coldness up the leg, but the circulation was still going on, and, of course, there was no line of demarcation. Dr. Sands proposed to amputate the limb to-morrow afternoon, if the consent of the relations could be obtained. The point which he wished to raise was, the proper treatment of such an injury in which there was rupture of a large vessel, as of the popliteal artery. Two methods of treatment had been proposed: one, to cut down and find the bleeding vessel and secure it; the other, to amputate the limb. So far as experience was concerned, the latter was the proper operation. It had been found under these circumstances exceedingly difficult to discover the bleeding vessel in the infiltrated tissues; it was found very often that both the artery and vein were ruptured, and cases in which that operation had been done, he believed, had proved fatal as a rule. One such case occurred to him in Bellevue Hospital in 1867. A lad of twelve years entered the hospital with an injury caused by a bank of earth falling on him. A diagnosis of rupture of the popliteal artery was made. Swelling took place very rapidly, the limb became cold, and after a while lost its vitality. In his case the operation of opening the popliteal space and tying the wounded vessel was proposed, but was not accepted. All operative interference was declined until twelve days after the injury, when, gangrene being evident, the parents consented to an amputation, which was performed at the middle of the thigh, and the boy made a recovery. An examination of the vessels in that case showed that the artery and vein were both completely ruptured at the level of the knee joint. From the rupture of a vein, of course, recovery might take place; but it was difficult, on account of the absence of pulsation and murmur, to make an exact diagnosis. There were some cases in which a large vessel was ruptured, and recovery took place spontaneously. He remembered the case of a man at Bellevue Hospital who had a fracture or a dislocation of the humerus into the axilla, he did not remember which. Within an hour after the injury the limb became enormously swollen in consequence of extravasation. A consultation was held, and amputation was proposed, but the patient declined it. Afterward the blood was absorbed, and the man made a very good recovery. A few years ago, while attempting to reduce a dislocation in a very old lady, he unfortunately ruptured a large vessel in the axilla. The swelling was very sudden and very great, and pulsation in the radial artery stopped. He was unable to say just what vessel was ruptured. The swelling extended down to the hand, and finally blood made its way down on the back of the pelvis. This patient also recovered. In a case like the present one, however, in which a large artery, as the femoral or the popliteal, was ruptured, he thought that the proper course to pursue would be to ligate the artery at once, if possible, if this alone were wounded; otherwise, to amputate the limb.

Dr. Post thought the course to be adopted in such a case would depend very much upon the severity of the injury. If it were inflicted by direct violence, producing very great contusion and laceration, the chances of saving the limb by securing the ruptured artery would be small. If the artery were ruptured by indirect violence, so that no very serious injury was done to the other tissues, he would suppose the prospect of giving relief by cutting down and securing the artery would be very fair. In the first instance the injury to the parts, without rupture of a vessel, would often lead to gangrene. Lately a patient was brought to him who had received a stab in the wrist from a pen-

knife. The wound was sewed up at the Chambers Street Hospital, but afterward the patient was brought to Dr. Post by a physician, with the statement that repeated hæmorrhages had occurred, that the limb was paralyzed, and that no pulsation could be felt in the arteries. The whole history of the case led Dr. Post to believe that the ulnar artery had been wounded. He applied an Esmarch bandage, cut down and ligated the ulnar artery. The patient left the hospital, and Dr. Post supposed he did well. He had not seen any cases of rupture of large arteries, as of the femoral or popliteal, in which the diagnosis was perfectly clear.

Dr. THOMAS M. MARKOE did not recall any cases exactly similar to the one mentioned by Dr. Sands. A patient once came under his care who had rupture of the anterior tibial artery in connection with a fracture of the bone. The evidence of traumatic aneurism was very marked, the swelling was great, but the case terminated favorably.

Dr. Post remarked that he had had two cases of compound fracture in which there was wound of the main artery, in one case the femoral, in the other the brachial. He tied the artery, and the patients recovered.

The PRESIDENT asked whether aspiration would decide whether arterial or venous hæmorrhage had occurred.

Dr. Post thought that, unless aspiration were performed very soon after the hæmorrhage had occurred, there would be no apparent difference between arterial and venous blood.

OBLITERATING INFLAMMATION OF THE CEREBRAL ARTERIES.

—The case was narrated by Dr. FRANÇOIS DELAFIELD. The patient was a man about fifty years of age, a sailor. He had been perfectly able to perform his duties until the 15th of September. Then, while sitting on a bench on deck, engaged in some work, he suddenly fell over to one side. He did not lose consciousness or become paralyzed. He was picked up, and after a little while was so much better that he could climb the ropes. Two days later, however, he noticed that he could not control his gait as well as before; he walked too fast, and ran against things. He continued in this condition, otherwise feeling pretty well, until the 24th, when he entered the hospital. Now there was also a little dragging of the left leg, and a little loss of power in it. Sensation was unimpaired. The motor power was good in the right leg and in both arms. He could speak fairly. He desired to go to bed. The next day his speech was a little affected; he articulated slowly and with difficulty. Motor paralysis remained confined to the left leg. He did not wish to get up or to do anything. On the 27th the speech was so affected that one could hardly understand what he attempted to say. The left arm was now almost paralyzed, and the left side of the face was a little paralyzed. By the first of October the patient had become almost completely unconscious, but he was not comatose. There seemed to be pretty complete paralysis of the whole of the left side of the body, and some involuntary contraction of the muscles of this side. He became more profoundly unconscious, and passed his urine and feces in bed. He remained in this condition until death, which took place on the 10th of October. There was no history of syphilis.

At the autopsy all the cerebral arteries were found to present the lesions of chronic obliterating arteritis in a very marked degree. The caliber of the arteries was very much narrowed; the right middle cerebral artery was almost obliterated. The white matter of the right cerebral hemisphere, just outside of the corpus striatum and the optic thalamus, was softened. The right corpus striatum was also softer than the left. The rest of the arteries of the body showed the ordinary lesions of chronic endarteritis in a moderate degree. There was but very little change in the kidneys. Those were the only changes which had occurred. The case was rather an unusually clear

example of the symptoms due simply to obliterating endarteritis of the cerebral arteries. In reply to a question by the President, Dr. Delafield said that syphilis might undoubtedly cause obliterating endarteritis, but he believed it was no longer questioned that the latter might occur independent of syphilis. This patient was a respectable man, who stoutly denied syphilis, and no lesions of the disease could be found.

Dr. A. BRANTON BALL had seen a similar case.

SALICYLIC ACID IN THE TREATMENT OF CYSTITIS.—Dr. WILLIAM H. DRAPEER related a case of cystitis in which he had used salicylic acid to advantage. [It will be given in a future number of the journal.]

Reports on the Progress of Medicine.

QUARTERLY REPORT ON OPHTHALMOLOGY AND OTOTOLOGY.

No. XII.

By CHARLES STEDMAN BULL, A.M., M.D.,

LECTURER ON OPHTHALMOLOGY AND OTOTOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, AND TO THE NURSERY AND CHILD'S HOSPITAL.

OPHTHALMOLOGY.

THE SECRETION OF THE HUMAN LACHRYMAL GLAND.—Magaard ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," lxxxix, 2, 1882) has been investigating the secretion of the lachrymal gland in man. His observations were made upon a man who had marked ectropium of both lids and of the external canthus of the right eye, and prolapse of the retrotarsal fold above and below, so that the mouths of the lachrymal ducts were visible. In the left eye the condition was even worse. As preliminary to his observations, the eyes were carefully cleansed with lukewarm water, until the parts gave a neutral reaction. Then the contents of the lachrymal gland were squeezed out, and, when tested, always gave an alkaline reaction. The results of his observations may be condensed as follows: 1. The lachrymal secretion is very variable in quantity, from various psychical and other causes. 2. By careful calculation, it was estimated that both lachrymal glands secrete in twenty-four hours 6.4 grammes of fluid. 3. Atropine diminishes the secretion in time. 4. Eserine annuls the action of atropine, and in a short time increases the secretion. 5. Irritation of the sympathetic nerve in the neck by the faradic current seems to accelerate the secretion. 6. The secretion coagulates by heat, and contains albumin and the chlorides, but no phosphates.

DIPHTERIC OPHTHALMIA AND ITS TREATMENT.—Barette ("Arch. d'Ophthalmologie," March-April, 1882) calls attention to two facts not hitherto mentioned—loss of the eyelashes, and paralysis of the lid. In the patients examined by him the ciliary bulbs were so altered by the disease that most of the cilia were lost, and were not reproduced. The only rational treatment consists in exciting in the mucous membrane a state of inflammatory congestion favorable to the elimination of neoplastic products and to the production of healthy pus, or, in other words, a purulent conjunctivitis; and then treating this purulent inflammation by the ordinary means in use. He removes false membranes, employs antiseptic lotions, and applies constantly hot fomentations. As an antiseptic lotion he employs either Labarraque's solution, or a solution of carbolic acid of five per cent.

TREATMENT OF SERPIGINOUS ULCER OF THE CORNEA.—Verdes ("Arch. d'Ophthal.," March-April, 1882) presents a somewhat novel view of the origin of this form of ulcer. He supposes an

obstruction in the course of the tears, or a certain amount of the force of the current, which becomes insufficient to carry along with it or to retard septic substances which may be engaged in the inferior orifice of the nasal canal, either spontaneously or by the patient blowing his nose; and these septic substances, *leptothrix buccalis* or *aspergillus*, will penetrate into the lachrymal canals, and, being in an excellent state for cultivation, multiply, and only await the proper moment for manifesting their necrotic action. He considers that the serpiginous form of ulceration is due entirely to the infection by micro-organisms which thus find a nidus of cultivation in the altered conditions of the lachrymal canals. He says that in the majority of cases the simple lachrymation precedes the corneal complications. These serpiginous germs may infect slight corneal desquamation, which were possibly produced by the obstruction to the course of the tears. He recommends the injection of intact lachrymal puncta with a four-per-cent. solution of boracic acid as the best prophylaxis against simple ulcers as well as the serpiginous. When such an ulcer appears he scrapes roughly its entire surface with a narrow cataract knife, and endeavors to produce an actual resection of the pultaceous margin, especially on the side where the destructive action seems to be going on. As the necrotic elements are detached, an assistant brushes over the cornea with a solution of salicylic acid and borate of sodium, each one gramme to ten grammes of water. Then the lachrymal punctum is opened, the point of an Anel's syringe introduced, and a series of injections made with a four-per-cent. solution of boracic acid. The conjunctival cul-de-sac is then carefully cleansed with carbolized cotton, and the solution of salicylic acid and borate of sodium again spread over the cornea. The eye is then covered with carbolized cotton. This dressing should be done twice a day. Bowman's operation may be done upon the lachrymal passages if deemed advisable.

AMYLOID DEGENERATION OF THE EYELID.—Raehlmann ("Arch. f. Augenheilk.," xi, 4) states that the first beginnings of the degeneration appear generally in the deeper layers of the conjunctiva, and here he has found the most marked degree of degeneration. It seems to extend in both directions, toward the epithelium and toward the tarsus. Still, all layers and tissues of the lid may be involved in the degeneration. In most of the cases examined, he found the conjunctival epithelium unchanged, but in a number of cases he observed that the cells had the peculiar hyaline glistening appearance. In several cases he noticed the first signs of hyaline degeneration and amyloid formation in the walls of the blood-vessels. The median cartilage is here generally more involved than the adventitia. The subconjunctival tissue is frequently the main seat of the disease, and in these cases sclerosis of the connective-tissue fibers plays an important part. In many cases of amyloid degeneration this seems to precede the peculiar degeneration of the fibrous connective tissue. The swelling of the tissues of the lid is generally moderate. The swollen parts feel hard, and are brittle. The broken surface has a granular appearance, and the granulations resemble frog-spawn or boiled sugar.

This tissue is colored reddish-brown by a solution of iodine. The color produced by the solution of iodine and sulphuric acid is in most of the cases not greenish, but rather a dirty brownish green or grayish white. The tissue in these cases are not very hard, but are elastic and resisting. The cut surface does not show a granular consistence, but rather a dense, brawny consistence.

The fibers of the connective tissue are not generally altered. The first signs of the amyloid degeneration are seen frequently in circumscribed spots in the continuity of the muscular fibers, and the fibers here have a nodular appearance, as if they were thickened, and lost their separate structure.

MODIFICATION OF THE OPERATION OF TRANSPLANTING THE CILIARY BORDER OF THE LID.—PARIS ("Arch. d'Ophthal.," May-June, 1882) recommends the following modification of Amannotakis's operation for the relief of entropion. He dissects up completely the ciliary flap from above downward to the free border, where it is only held by the mucous membrane. He then dissects up and pushes upward the fibers of the orbicular muscle by means of a blunt hook. He then fixes the ciliary flap to the suspensory ligament of the lid by means of needles armed with a suture. In cases of inveterate trichiasis with involution of the tarsus he adds to this operation a tarsotomy, in which the transverse section is made, of course, before the application of the sutures.

GLIOMA OF THE RETINA.—PONCET ("Arch. d'Ophthal.," May-June, 1882) records some interesting facts in connection with a case of retinal glioma. He thinks it singular that, in a tumor which returns as rapidly as glioma, we so seldom meet with cells with a segmented nucleus or a double nucleolus, and, therefore, he thinks that the rapid growth of glioma can not be attributed to this mode of evolution. In the case seen by Poncet the sclera was healthy, as was also the cornea, but Fontana's space was obliterated and the iris atrophied. The walls of the blood-vessels were the seat of the formation of giant cells. The neoplasm was in the vicinity of the ciliary processes, and in the midst of the hemorrhagic exudation, in the posterior segment of the eyeball, were masses of glomatous cells, irregularly scattered through the vitreous. The ciliary muscle was atrophied, but not glomatous. In the choroid the internal limitans was intact, the capillary zone was but slightly affected, and the glioma was mainly developed in the deep layers of the choroid, nearest the sclera. In the optic nerve the elements primarily the seat of the degeneration were the cells of the neuroglia, and the nerve fibers had become granular by the pressure exercised by the neoplasm. From the masses of cells in the immediate vicinity of the disc, and the condition of the optic nerve, Poncet regarded it as certain that the disease began in the papilla. In the blood-vessels the first tissue affected was the endothelium, and here the proliferation started. This he regards as a proof of the epithelial nature of glioma. He also thinks that glioma may be propagated as well by the grafting of one cell, or even of the granulations of protoplasm, as by dichotomic division of the nucleus. He found that when the retina remained attached to the choroid, the march of the neoplasm was very rapid, but, when the retina was detached, the progress was less rapid, and the eyeball retained its shape longer. The detachment is a mechanical act; a formation of adhesions by epithelial desquamation, a more or less thick, fibrinous exudation in greater or less abundance, a glomatous perforation in the choroid so situated as to retain the retina in place, would all hinder the detachment and favor the propagation of the neoplasm; but these are all entirely accidental. Whenever this tendency to detachment occurs, the disease is isolated in an exudation for a certain time before it involves the other membranes by grafting or cell migration. If enucleation is done at this period, a return of the disease is certainly postponed, and perhaps prevented.

DIVISION OF THE SPHINCTER IRIDIS WITH THE SPHINCTEROTOME.—MAKLAKOFF ("Arch. d'Ophthal.," May-June, 1882) recommends the operation of sphincterectomy, and describes an instrument for its performance, which consists of a small hook, made of silver or flexible steel, and so small that it can be introduced through a very small incision in the cornea. The pupillary margin of the iris is seized and brought out through the corneal incision, and then excised, so that the circular pupil is transformed into an oval. He has had this hook adapted to Wecker's scissors, so that it may be introduced through a small corneal wound, the iris sphincter hooked and drawn out through

this wound, between the open blades of the scissors, which are then closed by the action of the thumb and forefinger, and the iris excised.

NEW RESEARCHES UPON THE SENSIBILITY OF THE RETINA.—Charpentier ("Arch. d'Ophthal.," May-June, 1882) draws the following conclusions from his investigations into the sensibility of the retina: 1. The minimum illumination necessary for the perception of small luminous surfaces is inversely proportional to their extent. 2. The minimum illumination necessary for the perception of large luminous surfaces is independent of their extent. 3. The limit of retinal surface beyond which the surface exerts no influence upon the luminous perception about corresponds to the dimensions of the fovea. 4. The same laws seem to be applicable to indirect vision. 5. We must distinguish between simple luminous sensibility and visual sensibility, or perception of distinct centers of luminous excitation. 6. Visual sensibility demands for its production more light than simple luminous sensibility. 7. Visual sensibility is not affected by obscuration of the eye. It is always produced by the same minimum of brightness in spite of the diversity of physiological conditions. 8. The perception of two luminous points is produced directly and without confusion when they are situated at a greater distance from each other than the breadth of the fovea. 9. The differentiation of two points illuminated by a pure color demands more light than the perception of this color, which itself demands more light than the simple sensation of light. 10. Within the limits mentioned, the differentiation of two points upon a black ground is independent of their brightness. 11. Within the same limits, the illumination necessary for the differentiation of two points upon a black ground is inversely proportional to their surface. 12. We may rely upon these laws for establishing the principle of a precise method of physiological photometry. 13. The method here indicated applies equally both to white and colored light. 14. The perception of colors is influenced by the extent of the colored surface; the smaller the surface, the greater the necessary illumination. 15. The relation which exists between the surface excited and the minimum illumination of the color is not simple, as for the luminous sensation. Sometimes the chromatic sensibility increases more rapidly than the surface, and sometimes more slowly. 16. If we take away from the quantity of light which has provoked the chromatic perception that which is necessary for the production of the primitive luminous sensation, we see that the remainder is independent of the colored surface. 17. The chromatic sensation is therefore once again differentiated from the simple luminous sensation. It is much easier produced for red than for blue, the only colors which he has been able to compare precisely.

ENCYSTED CAVERNOUS ANGIOMA OF THE ORBIT.—ELONI ("Arch. d'Ophthal.," May-June, 1882) reports an interesting case of encysted cavernous angioma of the orbit, occurring in a woman aged fifty-two, of three years' duration, coming on without traumatism, but connected, he thought, with naevi of the lid, which existed in childhood. There were marked tinnitus aurium, an audible bruit, and marked diminution of vision. A naevus also appeared in the lower lip, and another on the calf of the left leg. There was also marked exophthalmos in a forward direction, but no diplopia. No ophthalmoscopic change. Eloni removed the tumor by excising the external angle of the conjunctival cul-de-sac, dividing the external rectus, and dissecting out the growth, of the size of a walnut, by the aid of a finger and the handle of the instrument. It was found completely encysted. The result was good, though vision was only eccentric, and the cornea became anasthetic over the entire supero-temporal quadrant. The eccentric vision, together with the narrowing of the vessels of the optic disc, and the gradual atrophy of the

quently. It is much more frequent among child-bearing women than among men. Oglesby has never yet met with a case in which a history of meningitis could not be obtained. In those cases in which effusion into the disc has rapidly destroyed vision, the optic tracts have presented direct evidences of softening.

THE HISTOLOGY OF THE CORNEA.—Hoene ("Med. Jahrb.," 1882, Heft 2) has been investigating the changes undergone by the *substantia propria* of the cornea by age, and his observations, made upon animals, have convinced him that the linear appearance in the cornea is due neither to the presence of lamellæ of connective tissue nor to the presence of a cementing substance. The fine threads which, under a high-power objective, are seen both longitudinally and in cross-sections, arise from the so-called plates or lamellæ, and penetrate the basic substance in all directions, giving off branches as they go, which again penetrate neighboring lamellæ. It is Hoene's opinion that these little threads are nothing more than the thread-like processes of the corneal corpuscles. A proof of this view, he thinks, is given by the fact that both threads and lamellæ in the cornea of new-born rabbits and dogs are stained by prolonged contact with the chloride-of-gold staining fluid. Observations upon older animals have led him to the conclusion that the processes of the corneal corpuscles, in the course of time, become altered into elastic plates and threads. The successive diminution and disappearance of the cells seem to indicate that the corneal corpuscles are gradually changed into the *substantia propria* until they all finally disappear in advanced life.

TUBERCULOSIS OF THE EYE WITH CONNECTIVE GLAUCOMA.—Falchi ("Ann. di Ottalmologia," xi, 2 and 3) reports a very interesting case of general tuberculosis of the eye, followed by secondary acute glaucoma, in a boy aged seven, of scrofulous family. The eye was enucleated, and a very careful microscopical examination made. From the clinical and anatomical examination of this case he draws the following conclusions: 1. Tubercles may be propagated in different parts of the eye and provoke an attack of glaucoma. 2. The cloudiness of the cornea in this particular case was due to the presence of œdema of the lymphatic spaces of the corneal parenchyma, especially in its posterior half, sometimes accompanied by disappearance of the connective-tissue elements, while the epithelium and anterior elastic lamina remained normal. 3. A fresh, young connective-tissue element with fibrinous coagula may be the medium of adhesion between the iris and the membrane of Descemet in acute glaucoma.

SPIRIOUS NEUROMA OF THE OPTIC NERVE.—Hulke ("Roy. Lond. Ophth. Hosp. Rep.," x, 3) reports an interesting case of tumor of the optic nerve in a woman aged nineteen, which was at first supposed to be a neuroma. It was removed with the eyeball, and was firm, spheroidal, and about one third as large as the eyeball, from which it was separated by a portion of seemingly healthy optic nerve about half an inch long. The extremely slow growth of the tumor was a remarkable circumstance. Except for some thickening, the dural sheath passed unchanged over the mass, but the loosely arranged fibers of the intervaginal space were enormously increased in the neighborhood of the entrance of the nerve into its front part. The new growth appeared to be a sarcoma, taking its rise in the loose tissue of the intervaginal space, most probably from the nucleated cells found upon its fibers.

IVORY EXOSTOSIS OF THE ORBIT.—Tweedy ("Roy. Lond. Ophth. Hosp. Rep.," x, 3) reports a case of ivory exostosis of the orbital and cranial cavities in a man, aged twenty-five, in whom the orbital portion of the growth was removed by operation. The patient died, thirty-two days after the operation, in profound coma. At the autopsy, the greater part of the exostosis was found in the left anterior cranial fossa. It had originally

sprung from within the left frontal sinus, and had grown chiefly upward. The roof of the sinus was in part extended over the tumor, and in part absorbed by it. In the frontal sinus were a few semi-transparent polypoid growths. The bony growth reached one inch above the orbital plate of the frontal bone, and extended for that distance into the left anterior lobe of the brain. It measured two inches from before backward. It also sent a prolongation about half an inch long downward into the left side of the nasal cavity, and this portion was broken off the remainder of the tumor, apparently at the time of the operation. Backward the growth had forced its way into the inner end of the great sphenoidal fissure. There was general basilar meningitis, with a little lymph in the fissure of Sylvius and at the anterior part of the pons Varolii. The brain in immediate contact with the tumor was in a state of red softening, being semi-fluid, with some puro-lymph on its surface at the summit of the bony mass. The case teaches that it is impossible, by the orbital portion alone, to judge of the real size and extent of an exostosis springing from the frontal sinus; and, consequently, that other indications must be sought for in considering the feasibility of removing the tumor by operative interference.

TUMOR OF THE BRAIN WITH OPTIC NEURITIS.—Lawson's case ("Roy. Lond. Ophth. Hosp. Rep.," x, 3) of tumor of the brain with optic neuritis, ending in death, occurred in a man who had just had a severe epileptic convulsion. Within an hour the convulsions recurred, and with great violence. Each convulsion lasted a few minutes, and was followed by an interval of coma. These recurrences continued for seven hours, and then ceased, the patient sinking into deep coma, which lasted for three hours. He then became violently delirious, remained so for several hours, and then fell asleep. When he awoke he had regained consciousness. From this time he remained free from all symptoms save severe headache for a period of five months. Then various symptoms, all pointing to tumor of the brain, made their appearance, and he slowly grew worse, and died in about a year after the first attack. At the autopsy the anterior third of the right hemisphere was found, to a large extent, occupied by a tumor of somewhat ovoid shape, two and a half inches long, two inches wide, and weighing about four ounces. Where it reached the surface it involved the posterior two thirds of the first frontal convolution and a small part of the middle of the second frontal. Below, it encroached upon the anterior part of the right lateral ventricle. There was marked softening of the brain substance surrounding the tumor, especially below and to the outer side. The tumor was remarkably dense and firm, very sharply defined, and readily separated from the surrounding brain tissue, though firmly adherent to the dura mater above. Its surface was smooth, rounded, slightly lobulated, highly vascular, and covered by a ramified network of small vessels. On section it was of a somewhat dark, fleshy-red color, rather paler toward the center, highly vascular, homogeneous and not encapsulated, slightly granular in appearance, and very firm to the touch. The vessels and nerves at the base of the brain were perfectly healthy, with the exception of the left optic nerve, which appeared flattened.

SYMPATHETIC OPHTHALMITIS FOLLOWING EXTRACTION OF CATARACT.—Milles ("Roy. Lond. Ophth. Hosp. Rep.," x, 3) reports a number of cases of undoubted sympathetic inflammation following extraction of cataract. The operation performed was Graefe's modified peripheral extraction. In six cases the operation was uncomplicated. In two some soft lens matter was left behind. In one the iris was partially torn from its attachment. In one the cataract had to be removed by the scoop, with slight loss of vitreous. As regards the condition of the exciting eye after the operation, in two instances there was simply a small incarceration of iris in the corners of the corneal section.

In one a dense membrane and posterior synechia formed as a result of iritis; in two iris and capsule were adherent to the wound; in two more the pupil was drawn up and closed by membrane; in one suppurative iritis of a painless character resulted; and in three instances suppurative irido-cyclitis occurred. The interval between the extraction and the onset of sympathetic ophthalmitis was, as a rule, two to three months. The shortest period was six weeks, the longest fifteen months. Keratitis punctata was invariably observed in the sympathizing eye, usually at an early period. In the sympathizing eye the tension varied from time to time. Several of these patients retained excellent vision in the exciting eye. The severity of the sympathetic ophthalmitis bore no proportion to the damage done to the exciting eye.

EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.—Benson ("Roy. Lond. Ophth. Hosp. Rep.," x, 3) reports a case of embolism of the central artery of the retina, occurring in a healthy person in whom no cause could be discovered. There was a complication in the shape of a cilio-retinal vessel. The line of demarcation between the cedematous retina round the macula and the normal patch to its inner side was extraordinarily sharply defined. The fatty changes in the retina occurred, with great rapidity, in less than three days. The circulation was eventually completely re-established, and the vision was rapidly restored by the use of electricity. Subsequently well-marked small round or oval white patches appeared in the region of the yellow spot and in the extreme periphery.

IRIDOTOMY OPERATIONS.—Miles ("Roy. Lond. Ophth. Hosp. Rep.," x, 3) suggests a modification of the operation of iridotomy, which consists in making the corneal incision in a radial manner, the outer end being at the sclero-corneal margin; that is to say, it is at right angles to the ordinary incision in the circumference of the cornea. The resulting scar is, of course, far external to the axis of vision. The advantages of this modification are: 1. That the incision in the cornea can be much more limited, and proportionally gives more play to the scissors. 2. That the knife can be plunged directly through the iris in the direction previously decided. 3. That the scissors are introduced and remain in the same direction, and, consequently, that they completely fill up the corneal incision, and so prevent any escape of vitreous.

SIZE AND POSITION OF THE LENS IN GLAUCOMA.—Bailey ("Roy. Lond. Ophth. Hosp. Rep.," x, 3) reports the results of his investigations into the size and position of the lens in glaucoma. He thinks, from his measurements and observations, which he has here tabulated, that he is justified in concluding that in glaucoma an enlargement of the lens is an uncommon and unimportant occurrence, and that its average diameter in this disease, whether it be cataractous or clear, is even somewhat below the normal at the corresponding period of life. He regards the vitreous body as the immediate agent of the advance of the lens, for detachments of this body by means of accumulations of fluid in front of the ora serrata appear to be as rare in glaucoma as in other diseases. The accumulation of fluid, either within or behind the vitreous, must be due either to the separation of an abnormally large quantity from the blood-vessels surrounding it, without a proportionate increase of that escaping from it into the vitreous chamber, or to an insufficient drainage in the last-mentioned direction, the quantity passing from the blood-vessels remaining unaltered. If a mechanical obstruction checked the outflow here, we should expect to find an accumulation of fluid immediately behind it—that is to say, between it and the vitreous, just as we find the posterior chamber distended when the pupil is excluded. Bailey asks, What proof have we that such a mechanical obstruction ever exists? Physiological variations in the size of the lens are not sufficient to produce one and,

moreover, the lens would require to be very considerably increased in diameter before it could by itself produce an obstruction. For the surplus fluids of the vitreous chamber pass forward, not between the lens and the summits of the ciliary folds, for the two touch under normal circumstances, but along the channels between the folds. It is clear that any influence exercised by the lens would be insignificant in comparison with that produced by the swelling of the ciliary folds themselves. Observation has taught Bailey that, so far from there being any enlargement of the latter, their average size is greater in eyes with normal or subnormal tension than in glaucomatous eyes. It seems indisputable that their size is directly influenced by the intra-ocular pressure, and it is highly probable that one of their functions, especially of their anterior or most projecting part, is to adapt themselves to, and to some extent regulate, the varying conditions of intra-ocular pressure. Bailey fails to recognize in cases of primary glaucoma any obstruction to the normal flow of fluid at the anterior surface of the vitreous sufficient to advance the lens. If we must have obstruction as a cause, we must look for it in the vitreous itself. But we find no evidence of this, at least in the cases where this body is not shrunken or altered in structure. The same may be said with regard to the retina in relation to the accumulations found behind it, not only with choroidal tumors, but in many advanced cases of primary glaucoma. If the increased contents of the vitreous chamber can not be attributed to a diminution of its normal outflow, we must fall back upon the theory first advocated by Donders—of an increased separation of fluid from the blood; that is, an exaggeration of the normal process.

ANATOMY OF THE ZONULE OF ZINN.—Benzel's investigations ("Arch. f. Ophth.," xxviii, 2) into the anatomy of the zonule of Zinn and pars ciliaris retine have led him to the following conclusions: 1. The pars ciliaris retine consist of cylindrical cells with a frame-work of fibers between, the latter appearing to be united with the vitreous lamella covering the inner surface of the pars ciliaris retine. This frame-work of fibers, like the elements of the retinal frame-work, is not digested by a solution of pepsin, though the cylindrical cells, the vitreous lamella, and the inner ends of the frame-work fibers connected with the latter, are digested by such a solution. 2. The vitreous lamella of the pars ciliaris retine is the prolongation of the membrana limitans interna. It covers the posterior surface of the iris as far as its pupillary edge. 3. The zonula originates by a small number of delicate fibers from the vitreous. 4. The zonula is closely connected with the pars ciliaris retine in the orbiculus ciliaris, and on the posterior part of the ciliary processes. In the central part the zonula is connected only with the points of the ciliary processes and the smaller elevations lying between them. In the anterior part the zonula is only connected with the points of the ciliary processes. 5. Between the zonule, the ciliary body, and its processes, are hollow spaces, formed by the zonula passing over the hollows between the processes instead of dipping down between them. These hollow spaces are connected with the posterior chamber, but have no connection with each other. 6. From the limitans interna and its prolongation, the vitreous lamella of the pars ciliaris retine, fibers run to the zonula, in a direction from behind and outward, forward and inward. The increase in the mass of fibers in the anterior part of the zonula is caused by the entrance of these fibers into the zonula. They run sometimes singly, and sometimes arranged in lamellae. In the middle and anterior parts of the ciliary body they lie in the hollow spaces between the processes of the ciliary body and the ciliary processes. 7. Delicate short fibers bind the zonula to the ciliary processes. They run partly forward, partly backward. 8. The ciliary body is not a solid mass, but is composed of nuclei and fibers, the fibers being the most numerous, and the nuclei being the most numerous, but in the center of

the newly born, and in the fetus of six or seven months, they are numerous. In one fetus of six months delicate capillaries were found in the zonula, but it was undecided whether they belonged to the zonula or to the vitreous. 9. The surface of the zonula toward the posterior chamber is covered with an endothelial membrane, which is demonstrable in a seven-months human fetus. It is also to be seen on the posterior surface of the iris, and on those parts of the posterior section of the zonula which are not adherent to the ciliary body. The mode of action of the fibers running from the zonula to the pars ciliaris retinae, which Berger calls the tensor fibers, is easily understood. These fibers are attached posteriorly to the posterior part of the ciliary body. Their anterior insertion is in the zonula. The contraction of the muscle of accommodation draws the posterior end of the choroid forward, and at the same time the posterior part of the ciliary body advances. By these changes the posterior insertion of the tensor fibers approaches the anterior insertion. By this change the tension of these fibers upon the zonula ceases. Up to this time the observations upon the living eye can not yet be made use of for deciding in what way the change of form of the ciliary processes during the act of accommodation influences the position and state of tension of the zonula. If we take into consideration the view that, in accommodation for the near point, the ciliary processes swell and approach the margin of the lens, it is evident that here the zonula is relaxed. But we can not deny the possibility that the ciliary processes during the act of accommodation recede from the longitudinal axis of the eye. If the ciliary processes in their anterior portion are drawn forward during the act of accommodation, a relaxation of the zonula may also result when the ciliary processes recede from the longitudinal axis of the eye.

HOMONYMOUS BILATERAL HEMIANOPSIA AND DECUSSATION OF THE OPTIC-NERVE FIBERS IN THE OPTIC CHIASM.—Marchand reports ("Arch. f. Ophth.," xxviii, 2) a number of cases of disease of the optic nerves and brain with homonymous bilateral hemianopsia which go to prove the theory of the decussation of fibers in the chiasm. In one case of optic-nerve atrophy in which successive microscopic sections were made of optic chiasm, nerves, and tracts, it was found that a portion of the atrophic nerve fibers, which at first ran in the upper region of the chiasm, and afterward in the middle region, were uncrossed. Another portion passed gradually to the opposite tract, and here appeared in the inferior region of the tract, and toward the inner side. The narrow border zone in the upper region of the chiasm, which at first appeared at the external border, next the uncrossed bundle of fibers, and gradually spread over the upper region of the tract of the same side, did not correspond to any atrophic zone of the other side. There must, therefore, be a system of commissural fibers, which can not be distinguished from the uncrossed bundle of fibers. Marchand thinks it certain that the uncrossed bundle contains the fibers for the outer half of the retina, but it may be assumed, from the shape of the visual defects, and from the by no means rare occurrence of a zone of transition between both halves of the visual fields, that the region of the macula and that part of the retina between it and the papilla receive fibers from both optic tracts. It is evident that the fibers which supply the lower part of the retina do not necessarily run in the lower half of the tract and chiasm. If there were complete destruction of the tract, the hemiopia would be complete; but it is different in partial destruction of one tract. If the fibers in the optic tract ran crossed and uncrossed through the entire cross-section, then large defects of any size of the tract would be constantly followed by entirely congruous defects of the visual field, for there would be the same number of fibers destroyed on the one side as on the other. This is gainsaid, however, both by the

results of anatomical examination and by the shape of the visual defects.

ACTION OF METALLIC FOREIGN BODIES IN THE INTERIOR OF THE EYE.—Leber publishes ("Arch. f. Ophth.," xxviii, 2) some further results of his observations upon the action of metallic particles in the interior of the eye. He has found that: 1. Particles of copper introduced aseptically into the anterior chamber excite purulent inflammation, but only when they are in contact with the iris. This does not occur when they are imbedded in the lens and project free into the anterior chamber. 2. If the particle of copper is suspended free in the vitreous, purulent inflammation does not arise; if it is lodged in the coats of the eye in the ciliary region, there results a circumscribed suppurative in the immediate vicinity of the foreign body. 3. Pieces of lead do not give rise to purulent inflammation either in the vitreous or in the anterior chamber. On the other hand, particles of lead suspended free in the vitreous produce the same form of detachment of the retina as is found in cases where particles of iron or copper have lodged in the eye. 4. Metallic mercury, introduced aseptically, causes violent purulent inflammation both in the vitreous and anterior chamber, which, however, is to be distinguished from septic inflammation by the fact that it does not extend to the remaining parts of the eye.

ANATOMICAL CHANGES IN CHRONIC INFLAMMATION OF THE IRIS.—Ulrich ("Arch. f. Ophth.," xxviii, 2) has been investigating the anatomical changes produced in the iris by chronic inflammation. He found a hyaline condition of the vessels in many cases, accompanied by more or less marked obliteration of their lumen. This was a marked symptom in leucoma adhaerens and in chronic iritis with posterior synechia, and to some extent in primary glaucoma. The obliteration of vessels and the fibrous thickening of the iris were the most marked pathological changes. Out of twenty-four cases, eleven were accompanied by increase of tension, and in ten of these there was hyaline degeneration of the iris vessels, with partial obliteration. Fibrous thickening of the iris was very pronounced in five cases of secondary glaucoma. It was also found in other cases without increase of tension, but where anterior synechia had existed for a long time. On the other hand, in cases where anterior synechia had not existed for a long time, as well as in cases of chronic iritis and keratitis interstitialis with iritis, the iris tissue was still in a state of hyperemia and cellular infiltration, but there was no increase of tension. Extensive destruction of the vascular region of the iris must lead to disturbances of circulation in the vessels of the ciliary body, and fibrous thickening of the peripheral portion of the iris must make the process of filtration of the aqueous humor in this region very difficult.

MAXWELL'S SPOT.—Mayerhausen ("Arch. f. Ophth.," xxviii, 2) has been investigating the subject of Maxwell's spot, and has found that, on looking through glasses which, besides the blue and violet, completely absorb all other rays, the appearance of the spot to his eyes differs in shape from that laid down in other observations. When he held before his closed eye a plane glass of the shade F of Nitsche and Gunther's scale and looked toward the sky, and suddenly opened the eye behind the glass, at the very moment of the entrance of the light he saw the extreme periphery of the Maxwell's spot constantly as a six-pointed star, instead of a circle or rhomb. In an albino whom he examined, in whom there was a total deficiency of pigment in the eyes, he found that the yellow coloring matter of the macula was present in normal extent and intensity.

PATHOGENESIS OF SYMPATHETIC INFLAMMATION OF THE EYE.—Deutschmann ("Arch. f. Ophth.," xxviii, 2) has been making some experiments as to the pathogenesis of sympathetic inflammation of the eyes by injecting the sheath of the optic nerve and the vitreous with a preparation of aspergillus spores in a three-

quarter-per-cent. solution of common salt. He found that, if the injection were made into the sheath of the optic nerve, on the day after the injection the papilla was very much injected, and the vessels markedly engorged and distorted, with all the signs of a papillitis. In some cases these lasted for several days, and then gradually subsided entirely, leaving a normal papilla. In others the inflammatory symptoms gave place, after a few days, to all the signs of atrophy, which in turn lasted for a few weeks, and then the vessels became gradually more distended and the papilla gradually regained a normal appearance. In the cases in which all the signs of papillitis were marked in the eye injected, there appeared in the fellow-eye, at a period varying between six and fourteen days, an engorgement and distortion of the papillary vessels, which increased so rapidly that in a very short time a marked papillitis was present. This lasted unchanged for several days, and then gradually subsided as in the first day, and the papilla regained its normal appearance. When the injection was made into the orbital tissue, a subsequent examination showed that an inflammatory process had been excited without any germination of the spores, as they were found unchanged, in the form of yellow nodules resembling tuberculous masses. The entire mass was adherent to the optic-nerve sheath, with moderate infiltration of the trunk and sheath of the optic nerve. In the sympathetically inflamed eyes the papillæ were swollen so that the retina seemed pushed off; they were infiltrated with nuclei, and this infiltration extended into the nerve-fiber layer of the retina. In some of these cases the pia mater in the anterior part of the base of the brain was infiltrated with lymph corpuscles. When the injection of the spores was made into the vitreous, there followed purulent inflammation of the vitreous, with violent symptoms, which, however, stopped short of panophthalmitis. Sympathetic affection of the fellow-eye appeared in seven or eight days in the guise of marked papillitis, which lasted for several days, and then subsided. An examination of these eyes showed purulent infiltration of the injected eye, with marked papillitis and interstitial neuritis, slight perineuritis of both nerves and of the chiasm, papillitis of the second eye, and infiltration of the pia mater in the anterior section of the base of the brain.

THE THEORY OF SQUINT.—In a paper upon the theory of squint ("Arch. f. Ophth.," xxviii, 2) Schneller states that a characteristic property of accommodative convergent squint is that the limits of the visual field remain still within normal conditions. He propounds the question whether every hypermetrope with good visual acuity and accommodation, and with normal muscles, the state of whose eyes is still found within certain specified limits, must necessarily squint? and answers it affirmatively, if the hypermetrope accommodates for the working distance. If, however, a hypermetrope is so circumstanced that he is not obliged to concentrate his attention on fine objects for any continuous period, he will not squint. Another causal factor to be considered in the production of squint is found in the degree of ability the persons possess of recognizing objects in circles of dispersion. This depends on, 1st, the width of the pupil; 2d, on the light-sense; and, 3d, on the psychic power of combination. A third factor in the causation of squint is the power of the accommodation. The power of fusion and the necessity for fusion of the images of the two eyes also play a very important part in the causation of squint.

CONGENITAL PARALYSIS OF THE SIXTH AND SEVENTH NERVES.—Chisolm reports ("Arch. of Ophth.," xi, 3) an interesting case of congenital paralysis of the sixth and seventh pairs of cranial nerves in an adult. There was complete congenital paralysis of the external rectus muscle on each side, causing in early life marked convergent squint from absence of muscular antagonism. In the operation performed at that time for the correction of

the squint, a myotomy was done instead of a tenotomy. The patient was never able to close the lids, from paralysis of the orbicularis palpebrarum. The skin of the face remained smooth, from paralysis of nearly all the facial muscles. In this case the sixth and seventh cranial nerves, according to Chisolm, have no cerebral origin. There is another possibility to be considered, however, and that is, the nuclei of origin may be normally developed, but the nerves themselves may not have developed at all, or may have developed for a part of their course only.

ON THE ARTIFICIAL RIPENING OF CATARACTS AND EXTRACTORS OF THE ANTERIOR CAPSULE.—Förster ("Arch. f. Ophth.," xi, 3) discusses the subject of the maturity of cataract, and also the means to be taken for its artificial ripening, such as pressure and coreolysis. He recognizes the fact that there are cataracts which have been mature for years, in which, however, the iris still throws a shadow, and the dilated pupil is more or less illuminable by the ophthalmoscope, while, on the contrary, there are cases of immature cataract in which the iris does not throw a shadow on the lens, nor does the dilated pupil give the slightest red reflex from the fundus of the eye when illuminated with the ophthalmoscope. Anatomical examinations would seem to prove that, after every cataract extraction, portions of the cortex are left behind in the capsular fold. But in all these cases the fragments of cortex float about loosely in the capsule, or outside it in the anterior chamber, and are, consequently, not subjected to a subsequent process of opacification and swelling. A mature cataract is one in which we can positively assert before the operation that there are no longer any cortical layers which will adhere to the capsule and undergo secondary opacification. An immature cataract is one of a consistence which experience teaches us is liable to be accompanied by a layer of cortex adhering closely to the capsule. Under the head of mature are included the great majority of cataracts in which there can be no doubt, and in which there are no sectors which shine like mother-of-pearl; and also those cataracts with a very large brownish-yellow nucleus which completely fills the capsular envelope, and with no cortex at all, or only a very thin layer. In some directions as to the *modus operandi* of extracting cataracts, Förster says that the best method of clearing the capsule after exit of the lens is to push the fine, straight-toothed forceps between the lips of the incision, and, by repeatedly opening and closing it, to endeavor, in the whole length of the incision, to catch the fragments of the capsule. He then makes gentle traction. He thinks it not only unnecessary, but even injurious, to cut off these capsular fragments, as has been recommended, for the fragments are then much more liable to become incarcerated in the incision.

PURULENT CONJUNCTIVITIS ARTIFICIALLY PRODUCED BY INFUSION OF JEQUIRY.—Wacker ("Kl. Med. f. Augenheilk.," Sept., 1882) has been experimenting with jequiry, and has found that an infusion of the drug used locally in the eyes is a good method of exciting purulent, or rather croupous, ophthalmia. The conjunctiva becomes markedly swollen and chemotic, and covered with a croupous membrane. The application is not painful, and produces a purulent conjunctivitis as a very rapid inflammation.

NEW METHOD OF TREATMENT OF THE LACRYMAL PASSAGES BY MEANS OF A DILATOR.—Hirsch ("Arch. f. Ophth.," Aug., 1882) recommends the use of a dilator for the treatment of a special dilator, not larger than a No. 10 bougie probe, to the bottom of the duct, and then withdraw it slowly, at the same time pressing upon a second dilator which separates the canal at two to such an extent that its rounded extremity corresponds to a No. 10 or 12 probe. This dilatation scarcely causes a trace of pain, and is relatively but little painful. This is repeated every five or six days, and this treatment rarely requires to be prolonged beyond a month or six weeks.

AN OPERATION FOR THE REOPENING OF THE OBSTRUCTED IRIS-ANGLE IN GLAUCOMA.—Grossman ("Ophth. Rev.," Oct., 1882) has been trying an operation which, while avoiding the drawback of iridectomy—viz., the deformity of the pupil—effects in a higher degree than iridectomy can do the reopening, or at least the easing, of the obstructed angle at the ligamentum pectinatum. With a paracentesis needle, provided with a stop, he punctures the cornea about half way between the free margin of the iris and the limbus, or about two millimetres from the latter. After the escape of the aqueous humor, he takes a club-ended silver probe, previously bent at the end like a button-hook, passes it into the anterior chamber through the corneal wound, the convexity of the hook being directed toward the ciliary region, and tries to push it gently but decidedly forward between the cornea and iris as far and in as large a circumference as possible. With the hook he gently presses the peripheral part of the iris back toward the lens, where a distinct resistance can be felt. He repeats this proceeding a few times, and, having done so in one quadrant, he turns the convexity of the probe round, and then presses in another quadrant. He then simply covers the eye with a bandage.

A NEW OPERATION FOR PTOSIS.—Wecker ("Ann. d'Oc.," July-Aug., 1882) describes a new operation for the relief of ptosis. He dissects up an oval flap of skin and orbicular muscle for a space of four or five millimetres in length along the free border of the lid. He then passes a suture through the skin above the eyebrow, about the width of the finger above the superior orbital margin, beneath the skin and muscular tissue, and brings it out at the upper part of the wound beneath the divided orbicular muscle. He then introduces the needle again beneath the orbicular muscle near the inferior margin of the wound, and brings it out through the middle of the bridge of skin just above ciliary margin. Then, making a bridge of five or six millimetres along the ciliary border of the lid, he passes the needle and suture in a reverse direction, and brings it out just above the eyebrow. A second suture is also introduced just like the first, and at a centimetre from it. Slight traction suffices to completely close the wound, and the two ends of each suture are then tied over a little roll of kid. The results have been very satisfactory.

(To be concluded.)

New Inventions, etc.

PORTABLE APPARATUS FOR SHOWER AND VAPOR BATHS, AND FOR DISINFECTING.

Among the many appliances used for giving Russian or vapor or spray baths, or for the purpose of disinfecting, there seems to have been, until recently, nothing adapted to either or all of these uses, at the same time combining those essential requisites, cheapness, portability, and easy adjustment to the bath-tub or wash-bowl faucet, by means of which one can have in one's own bath-room or chamber the ready means of taking a vapor bath, or disinfecting the atmosphere of the sick room or rendering it moist—conditions imperatively demanded in certain forms of disease.

The *Portable Hygienic Vapor and Disinfectant Apparatus*, now in use at two or more of our city hospitals and in several private dwellings, has been found to meet the requirements referred to.

For the vapor or simple shower or needle bath, the apparatus consists of a metallic tube about three feet long, an inch in diameter, perforated with many minute holes, and hung upon hooks at the top and side of the bath-tub. One end of the tube is closed, the other connected, by means of a rubber pipe ending in a Y, with the hot and cold water faucets, to which it is attached by an adjustable bib or coupling

arranged to fit a faucet of any ordinary size. When the cold shower bath is desired, one has but to turn the cock of the cold-water faucet (or of both the hot and cold if it is advisable to moderate the temperature of the water), and hundreds of minute streams issue from the perforated tube. When the vapor bath is needed, the bather, seated at the end of the tub, out of reach of the hot streams, on a chair made for the purpose, and under a canvas or rubber cloak fastened at the neck and covering the tub, turns on the hot water, the steam from which is confined by the cloak. For the purpose of medication, or the employment of disinfectants, are two cups—one for solids, the other for liquids. The former is of metal, and contains the drug or article through which the water passes before reaching the perforated tube. The cup for liquids is of glass, connected with a metallic air-chamber, so arranged that the liquid is fed, drop by drop, against the pressure of the water, until the cup is emptied. The ingenuity of the inventor (a lad of sixteen) is here apparent. For direct inhalation of vapor, the apparatus, constructed somewhat like the ordinary shower bath, is adapted to the wash-basin faucets, and the vapor inhaled through an opening in a cloak made for the purpose.

The apparatus is on exhibition at the rooms corner of Thirty-first street and Broadway, under the Grand Hotel.

A PHYMOSIS FORCEPS.

By J. H. GIRDNER, M. D.

As I have already published a description of this forceps, I will not now speak of its mechanism, but will add a few words of explanation as to the manner of using the instrument.

Grasp the penis between the thumb and forefinger of the left hand, and draw the prepuce as far back as possible, or until the muco-tegumentary junction forms the boundary of its opening. The instrument is taken in the right hand and the blades are pressed together until the

points are completely closed, when it is introduced into the preputial opening until the bars have passed just within the opening above and below.

Now the grasp on the instrument is slowly relaxed, and the spring, pressing the jaws apart, causes the barbs to transfix, first the mucous membrane, and then the skin. Now traction is made on the instrument, and the skin and mucous membrane are both drawn out together, and are cut off at one stroke just in front of the glans penis; they both recede together, and, when the sutures are applied, the edges coaptate perfectly, having been cut at the same stroke, and unite by first intention in from twenty-four to forty-eight hours, leaving no cicatrix, as when union takes place by granulation. If Ricord's forceps is used, or any of the others found in the shops, which take hold of the skin outside, it will be found that the skin rolls on the mucous membrane through the medium of the large amount of loose areolar tissue between these two surfaces, and the incision includes only the skin, which recedes and leaves the mucous membrane still covering the glans, which requires to be slit and turned back. Even then it does not accurately fit the cut edge of the skin, and must heal by granulation, thus leaving a scar, to say nothing of the slovenly appearance of the operation.

This forceps can be had of Mr. W. F. Ford, Mr. J. Reynders, or Messrs. George Tiemann & Co., all of this city.

Miscellany.

MALARIA IN SKIN DISEASES.—Dr. Lunsford P. Yandell, of the "Louisville Medical News," writes as follows: "Some time since the following paragraph appeared in the 'Michigan Medical News,' and has been widely copied in the medical journals of the country:

"A century ago John Hunter divided all skin diseases into three classes, one of which is cured by mercury and the iodides, a second by sulphur, and a third class which the devil himself can't cure. Dr. L. P. Yandell, who quotes Hunter as above, is given credit for a much less complex classification than even this. He attributes all skin eruptions to malaria. Quinine is a specific for malaria; ergo, quinine is the remedy for all skin eruptions. Q. E. D."

"I trust that my confrères of the press will do me the kindness and the justice to publish the correction now given, as the matter is not only one of personal interest to the writer, but is of scientific interest to the profession. The subjoined extracts are from a supplement to a report read to the American Dermatological Association, September, 1877. A copy of this report will be gladly sent to any one desiring it:

"From the criticisms which have been made on my views, I find that I have not succeeded in making myself perfectly understood. What I have contended for, and what I have reiterated, is simply this: Malaria is the *chief* source of acute skin disease. Scrofula is the *chief* source of chronic skin disease. The more inveterate cases of skin disease are often due to the co-existence of these two things. The specific exanthems, of course, are not included here, but I contend that their progress and termination are often largely influenced by the presence of malaria, or struma. I do not claim that malaria and struma are the *sole* causes of the dermatoses. Indeed, many of the dermatoses may exist *independently* of malaria or struma, and most frequently some exciting cause is necessary to develop the cutaneous eruption. Among the exciting causes are irritants, injuries, insufficient or improper ingesta, vicissitudes of temperature, alcohol, dentition, menstruation, parturition, lactation, etc. The proofs of the truth of my views are, in the first place, that the diseases of the skin are cured more certainly and more quickly by the antimalarial remedies on the one hand, and by the antistrumous on the other, than can be done by any other line of therapeutics; and, in the second place, that careful and painstaking investigation will, in the majority of dermatoses, make apparent the existence of the malaria or the struma, as the case may be.

"In conclusion, I desire to impress upon the reader that my views are not confined to the skin diseases. What produces disease here will produce it in all other organs of the body. What is true of dermatology is equally true of gynecology and ophthalmology and otology, and it is just as true of the diseases of all the other regions of the body."

"Subsequent observation has confirmed the truth of the correctness of these views."

THE NEW YORK SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—The annual statement of the affairs of this society for the year 1882 shows that the members now number one hundred and forty-two, of whom ninety-four are for life, and forty-eight annual subscribers. The number of benefactors living is twenty-two, of whom one is a layman; deceased, thirty, of whom six were laymen. The society has extended aid to thirteen widows and four children of deceased members during the year.

The financial condition of the society (as audited) for the year ending September 19, 1882, is as follows:

Total Assets, September 15, 1881.....	\$135,459 68
RECEIPTS.	
Interest on Mortgages and from United States Trust Company, etc.....	\$6,331 79
Dues and Initiation Fees of Members.....	1,575 00
Legacy from Estate of Simeon Abrams.....	2,248 70
	\$10,155 49

DISBURSEMENTS.	
Annuitants.....	\$4,288 00
Indispensable Expenses—Postage, Printer, Safe Deposit.....	84 68
Making Total Disbursements.....	4,372 68

Which, deducted from Receipts, leaves a Net Increase of, 5,782 81

Making Total Assets September 19, 1882..... \$141,242 49

Dr. Edward C. Seguin, at a stated meeting of the New York Academy of Medicine, held November 16, 1882, the following preamble and resolutions, reported by a committee appointed by the president at a former meeting, were read and adopted:

WHEREAS, Dr. E. C. Seguin, an eminent physician of this Academy, has been stricken with a domestic calamity so overwhelming as to paralyze him with despair, and so heartrending as to command universal compassion; therefore,

Resolved, That the Academy of Medicine do by its Seguin the expression of its profound sympathy and condolence.

Resolved, That while the Academy cannot do aught to relieve which this tragedy has befallen him, yet, in the path of his career, it will cherish the hope that Dr. Seguin may recover the spirit and the strength to return to his home, and take up his abode in the sphere in which he has formerly moved with such successful results.

Resolved, That a copy of these resolutions, signed by the president and secretary of the Academy, be forwarded to Dr. Seguin, and be published in the medical journals of this city.

QUINOLEINE.—This artificial alkaloid, C_9H_7N , made by distilling quinine or cinchonine with potash, has been studied, as regards its physiological and therapeutical effects, chiefly by Donath, von Jaksch, and Biach and Loimann; and what is known of them is briefly summarized by an anonymous writer in a recent number of "Le Progrès Médical." The leading physiological effects are: a notable lowering of the temperature, irregularity and diminution of the respiratory movements, nausea and vomiting, a sense of humming in the ears, and a feeling of pressure at the nape of the neck. Poisonous doses produce increased frequency of respiration, diminution and finally abolition of reflex excitability, complete paralysis, and death, often with pulmonary hyperemia and oedema. The alkaloid and its salts have antiseptic properties, and might be used as a substitute for quinine, over which they have the advantage of being cheaper.

The tartrate and the hydrochlorate are the only salts of quinoleine that are employed subcutaneously. According to von Jaksch, who has used the hydrochlorate hypodermically in doses as large as three grains, such injections are painful, and are often followed by rather extensive infiltration of the subcutaneous tissue. The tartrate is to be preferred; it is of a pale color, has a less pronounced odor, and is soluble in water and in alcohol, but not in ether. The medium dose, as a subcutaneous injection for an adult man, is from three to fifteen grains.

With varying results, the salts of quinoleine have been used in intermittent fevers, neuralgias, typhoid fever, whooping-cough, tuberculosis, pneumonia, erysipelas, septicæmia, etc. Their real value can not yet be stated, and further investigation is desirable. For their history and chemistry, references are given to Würtz, "Dictionnaire de Chimie," t. iii, and to an article by Skraup in the "Monatshefte für Chemie," 1881, p. 139.

DEATH OF M. DAVAINE.—In a recent number of "Le Progrès Médical" we find a note announcing the decease of M. Davaine, at the age of seventy years. Davaine's contributions to helminthology are well known, and the journal alluded to credits his writings with having played a leading part in clearing up the question of the anthrax group of diseases in man and in the lower animals.

MEDICAL EXPERT TESTIMONY.—It is doubtful if a physician is ever placed at greater disadvantage before the public than when occupying the witness-stand as an expert. His audience is usually critical and exacting, and any lack of dogmatism and promptness in his testimony is usually attributed to imperfect and inexact information upon his part. The fact that most physicians are unaccustomed to discussing professional questions before lay audiences adds to the difficulties of the situation, and the embarrassment of a cross-examination by a shrewd attorney often involves the witness in doubtful and ambiguous statements concerning familiar facts of medical observation. Hence the situation is a most trying one for those best qualified to testify upon any given branch of medical science and practice, and criticism in any given instance should be lenient.

It is always a matter for regret, however, when an overweening desire for notoriety induces a medical man to take the stand to testify relative to scientific matters in which his information is inexact and untrustworthy. Under such circumstances he is almost sure to bring disaster upon his own reputation, and to seriously damage medicine as a science in the public estimation. Such a case has recently occurred in Michigan, in which a physician was so imprudent as to appear as a witness for the plaintiff in an action against a brother physician for malpractice. According to the published account of the testimony, this widely known physician confessed under oath to a very limited knowledge of anatomy, and, in response to a question, admitted that he had never seen nor treated such a case as the one under consideration.

Such an exhibition is always damaging to the highest interests of the profession, and mortifying to its members. Before mounting the witness-stand physicians should be thoroughly posted in all the details of the questions at issue, and should speak dogmatically only concerning those features of the case in which they are qualified to substantiate the statements made. To speak long and learnedly in response to questions is always enticing; to be brief and cautious is wise.—*Louisville Medical News.*

AN ARMY SURGEON ON SHOES.—At a recent meeting of the Hygienic Congress at Geneva, says the "Scientific American," Colonel Ziegler, who is chief surgeon of the Federal army, read a paper on the evil effects of badly made shoes, with special reference to hygiene and the marching power of soldiers. Colonel Ziegler mentioned that the Swiss examining surgeons were compelled to reject every year 800 recruits—the strength of a battalion—for malformation of the feet, resulting from badly fitting shoes. The foot is in reality a bow, so elastic that, at every step, it contracts and expands, lengthens and shortens, and a line drawn through the center of the great toe intersects the heel. But shoemakers, who are generally utterly ignorant of the anatomy of the foot, do not give room enough for the lateral extension of the great toe. They crib, cabin, and confine it until it is forced against the other toes. Hence arise frequent inflammations of the great toe, corns, ulcerations, and sometimes veritable articular inflammation. Another evil which Colonel Ziegler ascribes in great measure to bad shoeing is flat-footedness, whereby the arch is converted into a straight line, and prolonged walking and marching are rendered impossible. Another cause of this defect is the habit of carrying heavy weights at an early age; but in most instances, Colonel Ziegler contends, perfect shoes would restore the foot to its normal condition. The first obstacle to a reform in the shape of shoes lies in the fact that it would involve a great expense in the shape of new lasts—an expense that shoemakers are naturally loath to incur. Fashion has also its lasts, and shoemakers consider themselves bound to conform to the prevailing mode. A test of a perfect pair of shoes is that, when placed together, they should touch only at the toes and heels; the soles should follow the sinuities of the feet, and, to give room for their expansion, should exceed them in length by fifteen to twenty millimetres.

PEPPERMINT OIL IN HERPES ZOSTER.—Dr. Meredith, of Birmingham, England, finds that peppermint oil, applied locally, is capable of rapidly allaying the pain of herpes zoster.—*New Remedies.*

MARINE-HOSPITAL SERVICE.—*Official List of Changes of Stations and Duties of Medical Officers of the Marine-Hospital Service, July 1, 1882, to September 30, 1882.*—HUTTON, W. H. H., Surgeon. To inspect keepers and crews, Life Saving Service, July 11, 1882. — MILLER, T. W., Surgeon. To inspect keepers and crews, Life Saving Service, August 7, 1882. — WYMAN, WALTER, Surgeon. To inspect keepers and crews, Life Saving Service. — LONG, W. H., Surgeon. Granted leave of absence for ten days, July 1, 1882. Granted leave of absence for fourteen days, September 16, 1882. — MURRAY, R. D., Surgeon. To proceed to Brownsville, Texas, August 21, 1882. — PURVIANCE, GEORGE, Surgeon. To inspect keepers and crews, Life Saving Service, July 13 and 18, 1882. To report for temporary duty at Washington, August 23, 1882. To report for temporary duty to Chairman, Board of Examiners, revenue bark Chase, at Norfolk, August 26, 1882. — SMITH, HENRY, Surgeon. Granted leave of absence for thirty days, July 5, 1882. — FISHER, J. C., Passed Assistant Surgeon. To report for temporary duty to Chairman, Board of Examiners, revenue bark Chase, at Norfolk, August 26, 1882. — IRWIN, FAIRFAX, Passed Assistant Surgeon. Granted leave of absence for thirty days, July 28, 1882. — CARTER, H. R., Passed Assistant Surgeon. To proceed to Hickman, Ky., for temporary duty, August 10, 1882. To proceed to Memphis, Tenn., for temporary duty, August 12, 1882. To proceed to Little Rock, De Vall's Bluff, and Newport, Ark., as inspector, September 16 and 21, 1882. — PORTER, F. D., Assistant Surgeon. To proceed to St. Louis, Mo., for temporary duty, August 21, 1882. To report to Surgeon Sawtelle for examination for promotion September 1, 1882. To rejoin his station (Chicago) when relieved by Assistant Surgeon Urquhart, September 1, 1882. — BENSON, J. A., Assistant Surgeon. To proceed to Cairo, Ill., for temporary duty, August 12, 1882. — DEVAN, S. C., Assistant Surgeon. To join revenue steamer Corwin for cruise in Alaskan waters, July 10, 1882. — URQUHART, F. M., Assistant Surgeon. To proceed to Wilmington, N. C., for temporary duty, July 26, 1882. To proceed to St. Louis, Mo., for temporary duty, September 1, 1882. Promotion.—PORTER, F. D., Passed Assistant Surgeon. Promoted and appointed Passed Assistant Surgeon by the Secretary of the Treasury, from October 1, 1882. September 14, 1882.

Lectures and Addresses.

LECTURES ON
HUMAN AUTOMATISM.

DELIVERED AT THE LOWELL INSTITUTE, BOSTON.

By WILLIAM B. CARPENTER, M.D., LL.D., F.R.S., Etc.

LECTURE I.

(Concluded from page 4.)

The *neurosis*, or physical action of the nerve-substance, has a very close relation to electricity; but, though electricity may imitate some of its effects, yet it is perfectly certain that nerve-force is quite distinct from electricity; and I only advert to their relation to clear your minds from any confusing idea you may have as to their identity. There is no doubt that both chemical changes and electrical changes occur in the working of the nervous system. It has been shown, for example, that, when light falls upon the retina, a chemical change, indicated by an electrical manifestation, is called forth; but that chemical change is really (I think) only the symbol of the nervous change, the *neurosis*. It is the nervous change which is the essential part; and it is only by the excitement of this *neurosis* that the psychosis can be produced. It is entirely through our bodily organization that our minds are kept in communication with the external world. Supposing all the inlets to sensation closed, the mind would acquire no knowledge whatever of that world. You are well aware of the case in this city—which has been a celebrated one throughout the world, owing to the admirable manner in which it was dealt with by my old friend, and your friend, Dr. Howe—in which the greater part of the inlets of sensation were closed, so that it was only through the touch that impressions could be received; and these, in the first instance, only drew forth the simplest and most elementary forms of mental activity. But, by the persevering use of the sagacious method devised by Dr. Howe, the higher forms of thought were awakened in Laura Bridgman through the medium of language, so that her mental life has not differed very considerably from our own; I mean, of course, as to its general character.

On the other hand, we may have an almost complete loss of the power of the mind to express itself in action. One organ after another may be paralyzed, and that paralysis may extend to everything but the parts of the muscular apparatus that are essentially concerned in the maintenance of those organic functions which build up and sustain the nervo-muscular apparatus—without affecting the activity of the mind, which may express itself to others, if only one single muscle remains obedient to the mental impulse. Some of you, I dare say, recollect in one of Dumas's sensational novels the case of an old man, the head of a family, who controlled that family, and especially prevented a marriage from being forced upon his granddaughter which was distasteful to her, by the simple winking of his eyelids, which was the only movement over which he retained any voluntary con-

trol. The movements of respiration, swallowing, etc., will go on automatically, as I shall hereafter describe to you, when all voluntary action is suspended; and the novelist does not seem to me to have gone beyond the possible truth in representing this old man as having no other mode than the winking of his eyes of expressing his mental determinations, and thereby governing his family.

It may have occurred to some of you, perhaps, as it has to myself a good deal lately, that our mental power is often exerted most strongly through the smallest of our muscles; and this alike in our ordinary daily communications, and in those which have the most important and wide-reaching influence.

Think what are the movements of speech. We are obliged to make use of the respiratory muscles; but, then, these are always in automatic activity; and what we do in speech is to exercise a certain regulation and control over them, so as to make the supply of wind (to revert to our former simile) conform to the demands of our vocal organs. But the muscles which are really employed in vocalization—in the production of vocal tones and in the articulation of language—are among the smallest in the body. Look, again, at the muscles of expression. The slightest twitch of the face may give the turn to the lives of two persons, who, without knowing it, are in that state of mutual attraction, which just needs the revelation of each to be made to the other, by (as it were) the closing of the circuit that shall bring them together. And so, again, the act of writing is mainly done by some of the small muscles of the fingers, the large muscles of our arms being used very little indeed. The same is the case in the telegraphic transmission of messages—a point that happened to occur to me not long ago, when Lord Granville telegraphed the order to the commander of the British naval force off Alexandria, "Bombard the forts to-morrow morning." If you think of the small twitches that were given by the telegraph clerk to the needles that conveyed that order, you will, I think, feel with me that scarcely a more "pregnant instance" could be adduced of the truth of one of the most pithy sayings of the great sage who has recently passed from among you: "Thoughts rule the world." Here was a thought that dominated a vast amount of physical power, and yet that domination was exerted through the smallest muscles of the body.

And I am thus led to another point which I hold to be of fundamental and essential importance—that there is no "common measure" between our mental and our physical activity. The chemical tests, the electrical indications, the mechanical measurements, which we have to base on the phenomena of muscular movement, will measure the physical energy that those muscles put forth, and the force of the *neurosis* which calls those muscles into action; but we can not thus measure the mental force which willed the movement, the force of the *psychosis*, which was the immediate antecedent of the *neurosis*. These two I hold to be utterly and completely *incommensurable*. True it is that we may to a certain extent measure the quantity of nervous tissue that is (to use the term in its physiological sense) "wasted"

in various forms of mental activity. The application of chemical tests to the kidney-secretion shows that there is such a "waste," and that its amount is in some degree accordant with the severity of the strain (so to speak) which we put upon our nervous organization. It would appear that the brain wastes more rapidly when we are fixedly directing our attention to a particular subject which we find it rather difficult to comprehend than when we are reading a pleasantly written book, the ideas of which we readily take in. This point was worked out a few years ago by my friend Professor Haughton, of Dublin, one of our "all-round" men, who is a good chemist and physicist, an eminent mathematician, and an able physiologist. Applying all this trained power to the investigation of the question, he came to the conclusion that, while a simple placid *exercise* of the mind would be attended with a certain amount of "waste," in proportion as the mind was made to *exert* itself in study by the fixed direction of the attention, and in proportion as that study was found more and more difficult, requiring more and more determination on the part of the subject of the experiment to master the ideas that the book conveyed, the greater was the "waste" of nervous tissue. But that does not give us any measure whatever of the *kind* of thought which was passing through the mind of that subject, or of the importance of its results. These results might be quite barren, or might be of the highest intellectual value. A fruitless attempt to solve a crabbed mathematical problem might produce as much "waste" of brain as was involved in the discovery of the law of gravitation or the invention of the differential calculus. And so of the moral power of those "thoughts that breathe and words that burn"—can that be measured by the amount of brain-waste? I remember once listening to a very able lecture, at the Royal Institution, by Professor Alexander Bain, who spoke of this correlation between the nervous waste and the thought upon which the brain was employed, as a thing that was so surely indicated that there could be no question about it; that we had not, it was true, demonstrative evidence of it, but that everything pointed in that direction; and he quite anticipated the time when our methods of research would be so refined and delicate that this relation would be clearly traced out. A friend sitting next me remarked at the close of the lecture: "It will be a very long time yet before we shall be able to measure how much bacon-fat went to the composition of 'In Memoriam.'" I think you will all feel that that remark was perfectly just and relevant. In the exertion of physical power we can trace its correlation with other forms of physical force; but there is no such measure for mental activity. Thus, when a muscle is called into contraction by the electric stimulation of its nerve, we can determine the amount of chemical change which takes place in the substance of that muscle, and the quantity of oxygen consumed in effecting it; and, by our previous knowledge of the mechanical and calorific equivalent of the amount of muscle-sugar consumed, it can be shown that the mechanical work done, *plus* the heat generated in the act of contraction, makes up the whole "energy" which that combustion can produce.

But does any one dream of being able to measure a

thought or feeling that does *not* express itself in muscular movement by any kind of balance or electrometer? Any such attempt seems to me to be utterly futile; a true "waste" of energy in a pursuit far less likely to succeed than the transmutation of metals or the production of diamonds; for both these things lie within the material sphere; while the sphere of mental action and the sphere of bodily action seem to me to be entirely separate and distinct, coming into contact only at that mysterious "junction" at which *neuroses* and *psychoses* are translated each into the other. That junction takes place over two lines; the one being that through which the physical impressions enter and are rendered into sensations; and the other that at which the volitions pass forth to express themselves in muscular movements. And I think that, if you keep in view that aspect of the relation of our bodies to our minds, you will find it to be the one which most completely accords alike with our own consciousness and with the general facts which we observe in the world around us.

Let us consider some of these leading facts. In the first place, no one who studies the mode in which hereditary qualities are transmitted, and traces the effect of their transmission in the whole mental life of the beings it affects, can doubt that there is through the body a certain shaping of the mental nature. On the other hand, it seems to me to be equally clear that the mental nature, properly trained and disciplined, can, as John S. Mill came to feel in later years, shape itself, and can not only shape itself, but shape the bodily organism. We have a familiar instance of this in the training of the bodily organism to do work which we can not do when we begin. We are constantly thus training ourselves—as in writing, drawing, music-playing, and the like. And I regard this relation of the body to the mind as very much that of the horse to his rider, who trains him to execute his behests, to turn at the twitching of his bridle, to stop when the reins are pulled in, and so on. By keeping that simile in view, I think you will find that you will come to a clearer apprehension of the mode in which that direction is exerted. The body is essentially, I think, automatic in its operation. We shall find our first evidence of this in the study of those movements which are immediately concerned in the maintenance of our organic life. If it were not, in fact, for the strict and pure automatism of those movements, we should cease to respire. Whenever our attention to them might be called off, our heart would cease to beat, the air-cells of our lungs would no longer be alternately filled and emptied, and we should not be able to swallow (as I shall hereafter show you), even by a volitional determination. The maintenance of our whole organic life is committed to a strictly automatic part of the apparatus; a certain voluntary control being given in some instances which renders that automatism subservient to our purposes. For example, we breathe regularly and slowly at a certain rate, which may be slightly modified by the exercise we take; we continue to breathe during repose, and even in the most profound sleep; and it is only when the action of poisons paralyzes the nerve-centers, or when the supply of blood to them is defective, that we cease to breathe. But, on the other hand, we have a certain control over our

movements of respiration; and it is by virtue of that control that we are able to use our organs of speech. Although I can not go on without breathing while I am addressing you, yet I can so regulate and time my respiratory movements that I can use the outgoing current for the purposes of vocalization; and I think we may draw from this act some very useful indications of the nature of bodily automatism, and the relation of the will to it, which will help us in conceiving of the same processes mentally.

Besides the ordinary automatism of respiration, there are several other respiratory movements which take place automatically under certain occasional conditions. If, for instance, I draw into my windpipe a crumb of bread or a drop of water, by the coincidence of an inspiratory movement with the act of swallowing, the presence of such a particle produces that violent explosive semi-convulsion which we call the act of coughing. This act consists, first, in the involuntary closure of the glottis, which is the outlet of the windpipe, and, secondly, in a sudden and violent spasmodic action of the muscles of expiration, the tendency of which is to drive forth the offending particle. If the entrance of an irritating gas is the exciting cause, the action is just the same.—Now, although the act of coughing is in itself purely automatic, yet it is one which we can reproduce by an act of the will. I can say to myself "cough," or can say to another person "cough," and a cough shall follow. I do not know how it may be in your Congress, but we know very well that coughs are sometimes got up in our Parliament to induce a troublesome speaker to "shut up"; and it probably falls within your experience that coughs are often intentionally used as little signals. On the other hand, we may sometimes be very desirous of controlling a cough, and may do so by an exercise of the will, if the automatic stimulus be not overpoweringly strong.

The point to which I would now specially call your attention is this—that the mental determination to cough exactly replaces the stimulus by which the cough is excited under ordinary circumstances. The change in the respiratory nerve-center which produces the muscular movement may be called forth either by an impulse transmitted through the afferent nerves which pass to it from the windpipe, or by the downward transmission of a similar impulse along what have been called the "nerves of the internal senses"—the fibers which descend from the convoluted substance of the cerebral hemispheres to the respiratory centers at their base. That substance is the instrument of our intellectual operations; and it is through these descending fibers that the results of our volitional determinations affect the lower portions of the nervous system. And just as one mode of excitement takes the place (as it were) of the other, so, as it seems to me, we are able to bring to bear upon a course of thought which is in itself automatic the same volitional direction or determination as we bring to bear upon the act of coughing. Just as we substitute cerebral action in the latter case for the stimulus which is brought to the nervous centers from the organ of voice, so we can bring the will to bear upon our course of thought and feeling; controlling, and it may be suppressing (as when we try to suppress a cough), that which we desire to

keep under, and exciting that which we wish to render predominant.

This may seem a little difficult to you just now; but I shall hope to make clear to you as we proceed that there is a close parallelism between the two modes in which the effort of mind thus manifests itself in directing and controlling an automatic bodily movement, and in directing and controlling the course of our thoughts or the play of our feelings.

And having spoken generally of the automatism of our bodies, I shall conclude this lecture by giving you a very simple illustration of it. I said that we had to train our bodies to execute our behests. You know perfectly well the training that the young child has to go through, first to make him stand upon his legs, and then to walk. When he has acquired that training by practice, the mechanism has been so developed, the physical conditions have been so shaped out in his nervous system, that this action will take place thereafter mechanically or automatically. We can *voluntarily* set our legs in action to walk, and we can voluntarily stop them at any moment; yet the walk shall go on automatically while our attention is otherwise engaged—in talking with a friend, for example. So long as we keep it up without fatigue, and, consequently, without effort, it is not a *volitional* movement. The distinction between volitional and volitional is a very simple but a very important one. The "volitional" implies effort; the "voluntary" only implies that we can control it if we choose to do so. You set out to walk with a friend, and you fall into conversation with him; your attention is entirely given to your subject of conversation; your thoughts and feelings express themselves in language, and are received, each by the other, through his auditory sense; your minds are engaged entirely upon the subject you are talking of; and your legs go on *of themselves* without your giving any attention to them; so that it may not be until you find yourselves come to the end of your walk, or perhaps in some place to which you did not intend to go, that you exercise any voluntary control over them, and "pull yourselves up." Now, on the other hand, if you take a long walk into the country, you may be after some time to feel that you can not prolong that walk without effort; your movements are no longer strictly automatic, but *make* themselves felt; you can not avoid feeling the fatigue that forces itself upon your attention; what, then, have you to do? You have to throw into every movement a distinct purposive effort; that "effort" is one of which we are *immediately* conscious; and we know that the feeling of fatigue which results from it is the mark and measure of the muscular energy that we throw into the action.

Now, here, again, we have a most striking parallelism between mental and bodily action. Our thoughts may be flowing freely without any constraint or control; we may be reading a book that interests us, and, if we readily take in its meaning, we do not feel it necessary to make any *effort* to keep our attention fixed upon it, our thoughts being automatically attracted to it. But some other object of interest comes in the way; a new book, for instance, comes in, which we should like to look at; or we hear a piece of music played that we should like to attend

to; and the temptation is strong to intermit the attention that we have been giving to the book. Now, to maintain that attention an effort is required. If we desire to complete our task, if we are determined to finish that book before we leave off, we intensify that desire by our own act, keeping our attention fixed on the book in opposition to the other attraction. And the sense of fatigue that we subsequently experience is, I think, the mark and measure of that effort; and the "waste" of nervous tissue that takes place will probably, as I just now said, more closely correspond with the effort it has cost me to fix my thought, than with either the quantity or the quality of the thought which has passed through my mind.

Original Communications.

A CONTRIBUTION TO THE SUBJECT OF THE REMOVAL OF THE UTERINE APPENDAGES (TAIT'S OPERATION) FOR PROLONGED MENSTRUAL TROUBLES, WITH RECURRENT PELVIC INFLAMMATIONS.*

By T. GAILLARD THOMAS, M. D.,

PROFESSOR OF GYNECOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

IN the issue of the "British Medical Journal" for July 29, 1882, appeared a remarkable essay by Mr. Lawson Tait, of Birmingham, England, enunciating views entirely at variance with those heretofore held by the medical profession, advocating pathological tenets which were altogether new, and recommending a plan of treatment which is at once original and bold.

This article was entitled "Remarks on the Diagnosis and Treatment of Chronic Inflammation of the Ovary," and I refer to it at some length to-night, first, because my own paper is based upon its suggestions; second, because I feel sure that the positions which it assumes will interest the Fellows of the Academy, even if they deny their validity; and, third, because I myself feel convinced that this bold and original surgeon has advanced views which are destined to open a new field for gynecological surgery in the future, and to exert upon this department of medicine an enduring influence.

I propose to give to-night, in as succinct a manner as possible, those points in the paper which are original with Mr. Tait; and I would say here that, while I do not by any means feel warranted by my own experience and observation in accepting all of them, I do believe that there is a sufficient amount of truth in some of them to make the essay one of the most valuable which this decade has produced for the gynecologist.

Since that period which constituted so remarkable an era in the history of gynecology—when Henry Bennet, of England; Simpson, of Scotland; and Marion-Sims, of Ameri-

ca, brought their eminent labors to bear upon this department of medicine—until the present time, a vast deal of attention has been directed to the uterus, the vagina, the uterine ligaments, and the pelvic peritoneum and areolar tissue; while diseases of the ovaries and Fallopian tubes have been left enveloped by a cloud of ignorance and uncertainty which few have endeavored to penetrate and dispel. Tilt, of London, the firm, persistent, and able advocate of the claims of ovarian pathology, has during this time stood almost alone, steadily and consistently enunciating views with which few sympathized, and still fewer indorsed and sustained. At the present time it may safely be stated that a wholesome revolution is occurring in this respect, that reflective men devoted to gynecology are now recognizing that a very large proportion of cases of menstrual disorder, pelvic neuralgia, and difficult locomotion, which were formerly attributed to the uterus, its ligaments, or the pelvic areolar tissue, are entirely due to ovarian disorder, and that hundreds of cases in which that devoted organ, the uterus, was cut, cauterized, and leached, had the same pathological origin. Mr. Tait's paper deals with this most prolific subject, and for this reason, added to those which I have mentioned, must be regarded as a most opportune effort to cast light where the darkness is most dense in gynecology, and to offer aid in a class of cases in which the operator in this department needs most assistance.

The following points may be given as the most original and valuable of the views enunciated by Mr. Tait:

1. He assumes that the view formerly held—that laparotomy operations should be postponed until absolute risk to the life of the patient rendered them necessary—should now be abandoned; and that, in the hands of an expert, they are at present so free from danger as to be justifiable even when life is not jeopardized.

2. That the usually accepted doctrine of the dependence of menstruation upon ovulation is wholly erroneous.

3. That the ovaries have nothing whatever to do with menstruation, and that this phenomenon is dependent upon the Fallopian tubes.

4. That many cases of abnormal menstruation are justifiably treated, and are relievable in no other way than, by extirpation of the ovaries and tubes.

5. That in chronic ovarian disease the tubes are invariably involved, and that in most cases it is the tubes which are chiefly at fault.

6. That the mortality in his last thirty-five operations having been only one, even this slight loss of life is susceptible of diminution in the future.

7. That many of those cases heretofore regarded as instances of menstrual, or recurrent, pelvic peritonitis or cellulitis, are really due to tubal dropsy and ovarian disease, an occasional discharge of the purulent accumulation of the former giving rise to slight and passing attacks of these affections.

This last statement Mr. Tait does not make in the paper to which I have alluded. I am indebted for it to my friend Dr. Emmet, who, in a recent visit to Europe, obtained it from a personal conversation with that gentleman.

As many of the Fellows of the Academy have paid little

* Read, with the exhibition of specimens, before the New York Academy of Medicine, December 21, 1882.

attention to the subject which engages us to-night, it may not be out of place for me to make a short statement concerning it which will make my paper more comprehensible, and at the same time give it an interest which it might otherwise lack.

Removal of the uterine appendages, as it concerns my remarks to-night, has nothing whatever to do with the subject of ovariectomy. The latter operation is resorted to for the removal of large and increasing tumors, which, if not removed, almost invariably destroy life within a few years. The former is generally performed for severe menstrual disorders and nervous troubles taking their origin in the uterine annexæ, which, while they do not jeopardize life, render it utterly miserable and intolerable.

The history of ovariectomy is well known; that of oöphorectomy, and the modification of that operation, which concerns us to-night, is so short that it may be summed up in a few sentences. In July, 1872, Professor Hegar, of Germany, first performed the operation of extirpation of the ovaries when not affected by tumors, and five days afterward it was performed by Mr. Tait, of England. Neither of these operations was published. In August of the same year, only one month later, Dr. Robert Battey, of Georgia, not only performed the operation as an original conception, but published it to the world, and obtained for it the consideration of the profession. The credit of establishing oöphorectomy upon a secure basis has therefore been justly accredited to him, although he was immediately preceded by two operators. The operation to which Mr. Tait lays claim, and which will in the future receive the name of Tait's operation, consists in the removal of the Fallopian tubes as well as the ovaries: *First*, because he believes that in that way alone menstruation can be controlled; and, *secondly*, because he regards tubal disease, salpingitis, and tubal dropsy as universally present with chronic ovaritis, and as being the more important of the two pathological factors.

In the short essay which I present this evening, I do not propose to consider Mr. Tait's views in an analytical manner. I intend merely to report four cases in which very grave menstrual trouble, accompanied by all the symptoms of recurrent pelvic peritonitis and cellulitis, were found due to tubal dropsy existing coincidentally with chronic ovaritis, exactly as Mr. Tait has described it as so often doing. This is all to which my paper pretends, for the cases reported are of too recent occurrence for me to draw any deductions as to the remote results of the practice of Tait's operation upon them.

CASE I.—Mrs. R. W., a colored woman, who was born in North Carolina, thirty years of age, menstruated at fourteen, has been married nine years, and is the mother of one child, eight years old, entered my service in the Woman's Hospital with the following history: Her menstruation was perfectly normal up to the period of weaning her child, eighteen months after delivery. In reference to the year and a half immediately following the birth of her child, no symptom bearing with any prominence upon her case can be elicited. At that time, in the intermenstrual period, she was taken with very sudden symptoms resembling those of cellulitis or peritonitis, accompanied by a

slightly bloody discharge from the vagina. This attack confined her to bed for one week, and since its occurrence she has been a confirmed invalid. Her menstrual periods have been painful, scanty, and irregular; she has suffered constantly from neuralgic pains in the pelvis; locomotion has been difficult, and standing so painful that she has been unable to gain a livelihood, or even to attend to her ordinary household occupations. She has had an attack of severe pelvic inflammation, similar to that already described, about once a year, almost invariably about the menstrual period. During the past eighteen months she has been almost constantly a sufferer from pain in both ovarian regions and across the back, headache, leucorrhæa, and, for the last six months, profuse loss of blood at the menstrual periods.

Upon examining her, I arrived at the conclusion that the case was one of menstrual or recurrent pelvic inflammation, due, as we have heretofore supposed these cases to be, to some unknown influence. As the uterus was large and anteverted, and gave forth too free a menstrual flow, I supposed that endometrial fungosities probably existed, and cautiously scraped the cavity of the body with the wire curette. To my surprise, very few and small fungoid growths were removed. I then endeavored to give relief to some of the existing symptoms by an anteversion pessary, but this attempt resulted in absolute harm. Upon more careful examination, I now detected enlargement over the site of the ovaries extending from the uterus toward the iliac bones, and strongly suspected that this was one of the cases of coincident ovaritis and tubal dropsy which have been so well described by Mr. Tait; and, as by observation I became more and more convinced of the truth of this conclusion, I decided upon an explorative incision, to be followed by Tait's operation, if the diagnosis were found to be correct.

Upon making an incision in the median line and passing two fingers into one iliac fossa, I drew up an ovary about as large as an English walnut, distended by a multitude of small cysts and a Fallopian tube resembling closely in size an ordinary sausage, and giving to the touch very much the feel of a loop of intestine. Tube, ovary, and ovarian ligament were ligated by an aseptic banjo-string, and removed. The same condition was found to exist on the other side, and the same procedure was adopted. I would remark here that this and all the other operations to be related were performed under the strictest antiseptic measures, with the exception only of the use of the spray during the operation.

On the thirteenth day after operation the patient was sitting up in bed, and recovered completely without a bad symptom.

The time of one menstrual period has passed for this patient, but as yet no sanguineous discharge has occurred.

I here show the ovaries and Fallopian tubes. The latter have greatly diminished in size since removal, but even now equal in circumference an ordinary spermaceti candle.

CASE II.—Mrs. W., twenty five years old, who has been married three years, and is the mother of one child, now eighteen months old, entered my service in the Woman's Hospital. Her menstrual periods began at the age of

seventeen, and before her marriage gave her no trouble whatever. Nine months after confinement she was taken with an attack of pelvic inflammation, which, from her description, seems to have been unquestionably one of slight cellulitis or peritonitis. Since the birth of her child she has never been well. She has always felt "dragged out," as she expresses it; suffered from constant pelvic pain, with occasional accessions of inflammation; has menstruated irregularly and painfully; and has suffered from constant leucorrhœa and difficulty of locomotion.

Upon examining her physically, I found partial laceration of cervix and perinæum to exist; discovered a mass the size of a hen's egg occupying the position of the left ovary; and detected such exquisite tenderness in the ovarian regions, and, in fact, all around the uterus, that I decided upon explorative incision, to be followed by Battey's or Tait's operation, if the case seemed to require one or other of these procedures.

Upon making an incision in the median line, the ovaries were found very slightly diseased, a few small cysts only existing within them, but the tubes were discovered to be distended by large accumulations of pus. Both the ovaries and tubes were removed, though with great difficulty, as firm adhesions bound the latter to the roof of the pelvis, which had to be broken by force.

I would here draw attention to the fact that, while Battey's operation may be performed without coincident removal of the tubes, the latter procedure can not be practiced without removal of the ovaries, for it would leave ovulation uninterfered with while removing the canal by which its products could reach the uterus.

This patient recovered without any remarkable rise of either pulse or temperature.

The ovaries and tubes are here exhibited in the phial marked Case II.

CASE III.—Miss F., aged twenty-two, entered my private hospital with the following history: She began to menstruate at fourteen, and from the first epoch has suffered from the most dreadful dysmenorrhœa. Until a year ago, pain was confined to menstrual periods, and was agonizing only for about thirty-six or forty-eight hours. For the last year it has been almost constant, lasting throughout the intermenstrual period, but greatly increasing at that time. The physician and friends described the menstrual suffering as being so very severe and exhausting that it was impossible for her to bear it unless she were kept semi-narcotized. At the last period, her physician, a very intelligent man, declared to me that for hours the pulse was scarcely perceptible at the wrist, and that he had feared a fatal result.

Upon physical examination, I found the ovaries tender, enlarged, and somewhat prolapsed, though not very markedly so. Of enlarged Fallopian tubes I could discover no traces. Some months previous to my examination of the case, Dr. T. A. Emmet examined it, and felt satisfied that he discovered evidences of pelvic inflammation.

In this case I had not the slightest hesitation in recommending Battey's, or, if found necessary, Tait's operation, and the friends of the patient very gladly consented to any

procedure, however dangerous it might be, which held out a prospect of relief to this suffering woman.

I removed both ovaries and tubes, for I found the former filled with small cysts, and the latter distended, their lining membranes inflamed and bathed with pus, which was not, however, confined within them so as to create dropsical enlargement. In place of this, that condition described by the older writers as profluent dropsy of the tubes existed. An ordinary lead pencil could readily be passed through them.

Unfortunately, the specimens from this case were destroyed.

The patient recovered without unfavorable symptoms, and, although the time for her next period is at hand, she is free from pain, and very much more comfortable than before operation. (This period was marked merely by a slight and painless bloody discharge.)

CASE IV.—Miss M., aged twenty-seven years, entered my private hospital, giving the following history: She began to menstruate at fourteen, and with severe pain. Until two years ago her case could have been classed with one of those very common ones of exceedingly severe dysmenorrhœa with which we so often meet, but at that time a sharp attack of pelvic peritonitis occurred, and since then she has been a most wretched invalid, having become greatly emaciated, suffering constantly, and being almost always confined to bed. During these two years she has had quite a number of attacks of pelvic peritonitis, which have uniformly occurred either just before or just after menstrual epochs. In September, soon after admission, one of these occurred, and the patient very nearly lost her life, the temperature, even under active repressing means, reaching 104.5° F. and the pulse 140. The great peculiarity of the attack was the excessive degree of pain by which it was accompanied.

Close observation of the rational signs of this case, combined with the physical signs, led me to the conclusion that it belonged to that class of cases with which I am dealing to-night, and the patient's friends, fully appreciating the more than ordinary dangers which attended upon the procedure in her case, gladly consented to the performance of Tait's operation, feeling, as did the patient herself, that death even would be preferable to the wretched existence which she was forced to endure.

The operation being decided upon, with the assistance of my colleague, Dr. P. F. Chambers, everything possible was done to increase the vital forces of our patient, but, after a month's treatment, we came to the conclusion that nothing could be accomplished by these efforts, for no sooner would we gain a little than a slight pelvic flurry would not only rob us of what we had obtained, but throw us backward. It was therefore decided to operate at once, as both Dr. Chambers and I felt satisfied that the patient, in her existing condition, could not live through the coming spring, and that the chances of operation would be better in the beginning of December than in that inclement season intervening between January and April, when the mortality of ovariectomy rolls up with such frightful rapidity in this climate.

In justice to Tait's operation, let me describe, as accurately and graphically as I can, the condition of this patient prior to operation. In emaciation, pallor, and depreciation of vital forces, she resembled closely a patient in the third stage of pulmonary consumption. Unable to walk even across the floor without assistance, she was constantly confined to bed with a temperature of 100° , a pulse of 115 to 120, a great deal of irritability of the stomach, with loathing of food and never-ending pelvic pain.

The operation was performed on the 11th of the present month. The ovaries were found not very much diseased, but having within their structure a number of small cysts. The Fallopian tubes, which are now shown, were in a condition of tubal dropsy from one quarter of an inch from the uterus to their fimbriated extremities, and throughout their whole extent were firmly bound down by false membranes, which had to be torn with considerable force. The operation was tedious and difficult, and at its conclusion no one who witnessed it could avoid making an unfavorable prognosis as to the result. Unfortunately, this was sustained, for in twenty-four hours one of those insidious attacks of peritonitis with low temperature and little pain—which we so often see develop after laparotomy performed upon very much enfeebled women—declared itself, and on the sixth day destroyed the patient's life. The tubes, which I now show, will be seen to be as large as ordinary sausages, to be filled with pus, and to be much twisted upon themselves.

This embodies all my experience in reference to this subject. As I have already said, I regret that the remote results of these operations are not yet at my disposal. All that I have aimed to do has been, as far as in me lies, to "hold up the hands" of an original and brilliant investigator, who, I sincerely believe, is working a most useful and prolific pathological vein.

If there be any here to-night who desire to exercise a spirit of criticism, believing that I have brought these cases before you in too jejune a form, let them do so upon our worthy president, who, a week ago, seized upon me with that relentless grip under the merciless nature of which so many of you have groaned in the past, and will, I trust, have an opportunity of doing still longer in the future, and insisted upon my making this preliminary report. Resistance was in vain, and I yielded.

A few words more in conclusion. Mr. Tait's immediate results from his oöphorectomy operations have been, like those of Keith, Wells, and several other European surgeons from ovariectomy, exceedingly gratifying. Out of seventy-five cases, his whole number in July last, he had only six deaths; out of the last sixty-one of these cases, only three; and out of thirty-five operations for pure chronic ovaritis, only one death.

In this country, alas! we have no such glorious figures to present. Dr. Battey's last report* was of fifteen cases, out of which he lost three; and out of my whole number of twenty-one cases I have lost four. The question as to why European statistics of laparotomy operations are better than those of our own country, the birthplace and the nursery of

this great surgical achievement, is equally interesting and important, and it behooves American operators to look to the matter most carefully. It is true that they may lull their misgivings to rest by listening to the kindly suggestions of a superior physque on the part of patients, a more advantageous climate, and the concentration of cases in the hands of experts on the other side of the Atlantic; but it is unlike the genius of our land to accept such placebos. Let us look the disagreeable truth frankly in the face, and recognize that, so far, at least, our European brethren are, in this field of surgery, for some unknown reason, ahead of us, and let us seek for and find that reason as soon as possible. The discrepancy which exists between our statistics to-day can not be met by argument; it must be abolished by results.

ALLOCHIRIA: ITS NATURE AND SEAT.*

By WILLIAM A. HAMMOND, M.D.,

PROFESSOR OF DISEASES OF THE KIDNEY AND BLADDER IN THE NEW YORK POST GRADUATE MEDICAL SCHOOL, ETC.

On the 4th of November, 1882, I examined, in conjunction with Dr. L. A. Stimson, and at the request of the Corporation Counsel, a gentleman who, it was asserted, had received a serious injury of the spine. It appeared that on the 27th of February, 1881, he was driving from the city to his residence at South Yonkers. It was a dark, foggy, and rainy night, and he drove into a ditch which the ice and snow had formed entirely across the road. The front axle of his carriage was at once broken, and he was jerked forward against the dash-board. The horses started to run, and dragged the vehicle, with him in the constrained position mentioned, for the distance of about two hundred feet before they were stopped. He then, not thinking himself to be severely injured, procured another carriage, and drove on, in his wet clothes, through the rain to his home, which he reached at about half past two o'clock the following morning. In a day or two, symptoms indicating spinal trouble began to be developed. He some time afterward consulted a physician of this city, who diagnosticated Pott's disease. This opinion was confirmed by a surgeon to whom the physician took him, and a plaster jacket was applied. Amendment soon began, and, finding the jacket uncomfortable, he removed it; but, his symptoms recurring, it was replaced, and, in addition, an apparatus designed to keep the head from resting directly on the vertebral column was applied.

Several months elapsed, during which he was at times better and at others worse. Upon the whole, however, there was no decided improvement. The fact that he had brought an action for injury to his person, and that the city was the immediate cause of my examination.

So far as I could determine from the history given me by the patient, I was satisfied that at no time had he suffered from injury of the vertebral column or subsequent Pott's disease. Certainly he exhibited no symptoms of that affection, when I placed him, and the surgeon who applied the plaster jacket testified at the trial, a month subsequently, that he was cured. Neither Dr. L. A. Stimson,

* Agnew's "Surgery," vol. ii.

* Read before the New York Association of Surgeons, January 2, 1883.

nor Dr. Hamilton, nor Dr. Clymer could discover indications of its existence. It is quite evident that he did not have Pott's disease on the 4th of November, when I saw him, or at any subsequent period, and exceedingly probable that he had never had it.

He complained, however, of pain throughout the whole spine, and of excessive nervous irritability. He had had contractions of the muscles of the lower extremities, and on causing him to walk about the room it was evident that his limbs were stiff, and that he lifted his feet with difficulty. His gait was very different from that of a person suffering from locomotor ataxia. The feet were not raised from the ground with a jerk and put down with the two distinct movements so characteristic of locomotor ataxia, but were moved as if they were weighted down with some heavy substance. The knee-tendon reflex was greatly exaggerated on both sides.

Up to this time no experiments had been made with the view of testing the sensibility of the lower extremities. These were now denuded of their clothing, and the patient was told to shut his eyes. The touch of a finger, the scratch of a pin, or a deep puncture with the blade of a pen-knife was equally unfelt in the right leg. On making the like experiments on the left leg, he complained of pain when the knife was stuck into it, and automatically carried his hand to the place which he supposed I had punctured, but, instead of touching the spot injured, he indicated the exactly corresponding situation on the other leg. Repeated experiments led to like results. He had sensibility in the left leg, but referred all impressions to the other side. Dr. Stimson assisted in verifying these results.

I came to the conclusion that the patient was suffering from antero-lateral or lateral sclerosis, with the implication of the posterior horns of gray matter, and probably of the membranes of the cord to a slight extent.

With the diagnosis, however, I have little to do at present, my intention being to restrict what I have to say to the crossed sensibility which the patient exhibited. To this condition the name *allochiria* (*ἄλλος, χεῖρ*) has been given by Professor Obersteiner,* of Vienna, who was the first, so far as I know, to call special attention to the phenomenon, though it had been incidentally alluded to by Leyden, and one or two others, as an occasional symptom of locomotor ataxia. A case following severe cranial injury has also been reported by Ferrier.†

Of Obersteiner's four cases, two were of locomotor ataxia, one was hysterical, and the other was the result of severe and direct injury of the spine. Death ensued in this last case, and, on post-mortem examination, it was found that there had been inflammation of the first, second, and third lumbar vertebræ, meningitis, and extensive transverse inflammation of the cord. The posterior columns, for a considerable distance above the seat of the injury, were in a state of sclerosis, and the posterior horns of gray matter in portions of the cervical enlargement were "transversely divided by a peculiar, structureless, transparent mass, intensely

colored by carmine, and very similar to the mass which is found round the larger vessels in inflammatory processes in the cord."

I have quoted Obersteiner's own language because I think it is to such a lesion of the posterior horns of gray matter as he describes that the phenomenon of *allochiria* is to be ascribed. Neither he nor Ferrier offer any explanation of the mechanism of its production. On the contrary, they declare their inability to do so.

Certainly *allochiria* is not a usual symptom of sclerosis of the posterior columns of the spinal cord. I do not think it is ever met with in uncomplicated cases of this disease, nor do I think it is a possible condition in such instances. For the complete understanding of the subject, a few words relative to the anatomy and physiology of the cord are necessary.

The posterior tract of gray matter is probably the only channel by which sensory impressions reach the brain, the posterior columns having, in their normal condition, nothing whatever to do with the transmission of such impressions. But, before reaching the posterior horns, the posterior roots of the spinal nerves pass through the columns of Burdach, and, when these are the seat of inflammation, as they are in locomotor ataxia, disturbances of sensibility, such as hyperæsthesia, paresthesia, and anæsthesia, are produced in the parts below by the pressure exerted upon these roots.

It is quite certain, as Brown-Séquard, Lockhart Clarke, Gerlach, and others claim, that there is an almost complete decussation of the sensory fibers within the gray matter—those from the right side of the body passing over to the left side of the cord, and *vice versa*. We are taught these facts, not only by experimental physiology, but also by the instruction we derive from the study of cases of disease or injury of the cord. Disregarding, as of no importance in the present connection, the fibers that do not decussate, we have in the accompanying diagram (Fig. 1) an explanation

FIG. 1.

of the phenomena: *a*, the left posterior horn of gray matter; *b*, the right posterior horn; *c*, the commissure of gray fibers; *d*, sensory fibers coming from the left side of the body; *e*, sensory fibers coming from the right side. A lesion of the right posterior horn at *f* would produce anæsthesia of the left side of the body, and *vice versa*.

Now, in sclerosis of that portion of the posterior column called the column of Burdach the lesion is almost always

A SIMPLIFIED EVACUATOR FOR LITHOLAPAXY.

By HENRY J. BIGELOW, M.D.,

SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL; EMERITUS PROFESSOR OF SURGERY IN HARVARD UNIVERSITY.

THE operation for the immediate removal of a calculus through a catheter, like many other surgical operations, can be accomplished more or less satisfactorily by any one of several instruments which much resemble each other. But it can be done better by employing a more perfect apparatus than those now generally in use. It has been said that "no new form of instrument is required by this operation," which is true so far as it implies that neither a lithotrite nor an evacuator is a new instrument. But it would be a mistake to infer that the operation could have been done with the instruments of the old lithotry, and that they had needed no change to adapt them to what is now required of them, or that they can not be still further modified to advantage. The new operation can not be performed with the old instruments. It requires a larger evacuating catheter than that of Clover, through which the usual product of the lithotrite could not pass, except powder and sand, and that only in limited quantities, because the other detritus obstructed the entrance of the tube.* Though at first received with a good deal of distrust, the large catheter has been finally adopted by all the surgeons who have done the operation, and, in fact, can not be dispensed with. It should be combined with a thoroughly efficient aspirator. But no particular form of aspirator has so far met with general approval. Though better than it was, surgeons have none as yet which entirely satisfies all requirements of the operation and is at the same time compact and convenient to handle, and simple in construction. This part of the evacuator still needs improvement.

* Sir Henry Thompson says ("Diseases of the Urinary Organs," Philadelphia and London, 1882): "The evacuating catheter to be attached to the aspirator should be as large as the urethra will admit; usually No. 15 or 16 of the English scale [26 to 28½ French] may be used without any danger. Sometimes No. 17 or 18 [30 and 31 French] are admissible; but such sizes are quite unnecessary for small stones, and may produce mischief; hence they are only to be used where the presence of a large stone demands corresponding instruments." Or, it might be added, to expedite the operation, when the urethra is large and healthy. The size of the normal urethra, according to Otis, is, if we except the meatus, 32 of the French scale. Clover's evacuating catheter was 21. Those now in use range from 26 to 31. Care, however, and often special skill, may be required to introduce safely the largest sizes; 31 is very rarely needed, and the French sizes 28 and 29 are generally the most convenient. For a final washing or sounding without anesthesia, when it is desirable to give the patient the least discomfort, even so small a caliber as 26 is sometimes useful. Through a catheter of this caliber Mr. Teevan has removed calculi weighing six or eight hundred grains, but such cases should be regarded as showing what is possible, rather than as establishing a rule of practice. Here I may add that, although no lithotrite compares in size with the larger tubes, it is yet true that long-bladed lithotrites, especially if they have the sharp extremity of the old instruments, are more difficult than tubes to introduce with safety. Although since 1878 my lithotrites have been made in three sizes, I have rarely had occasion to employ any other than the middle size.

The usual parts of an evacuator, not including the catheter, are these:

1. The exhaust, the best form of which is an elastic bulb.
2. A space or trap for air, at the upper part of the instrument.
3. A glass receiver at the lower part, to collect and show the *débris*.

In drawing out fragments from the bladder through the large catheter, one bulb or aspirator, if strong enough, is about as efficient as another. An aspirator of almost any shape, and having almost any combination of its parts, will do this. So will a mere elastic bulb attached directly to the catheter, without joints or receiver, if it is placed lower than the catheter, bent down like the body of a retort, so that the fragments can fall to the bottom of it; and the instrument will still work well if it has joints made, for economy, of cork or rubber instead of metal. But, however otherwise arranged, a satisfactory aspirator should have:

4. Some device, near the catheter, to act as a trap for *débris* and secure every fragment that has passed it.

The chief difference among evacuators, now, is in the certainty with which they retain the fragments they have aspirated. Any instrument will draw out the fragments, but few hold them securely, for the *débris* do not always fall into the glass receiver, nor do they always remain in it. On the contrary, they are easily carried back to the bladder. This defect in the action of the evacuator has received little attention from surgeons, although it is the only point connected with the instrument which offers any difficulty whatever. Until recently it has been remedied only by sacrificing simplicity in the apparatus.

In endeavoring to make a satisfactory evacuator for litholapaxy, many experiments have to be tried. It is quite possible that a perfectly satisfactory instrument might have been contrived some time ago, if it had been generally understood that an evacuator that works best with pieces of broken coal in a vessel of water will succeed best with the fragments in the bladder.* So also will the surgeon if he is otherwise well qualified. It is true that the living tissues are easily injured, but in other respects the experiment can be made sufficiently like the operation to give it great value. Aspirating *débris* from the bladder is not a question of pathology, but of operative surgery—of physics. And, in view of the fact that we fail, in some bladders, to discover a last fragment even by repeated washing, an evacuator should be so constructed that it will absolutely prevent a fragment that has once passed the catheter from returning to the bladder to become the nucleus of another calculus.

It is not altogether easy to meet this requirement, because the solid particles are usually borne back and forth with the current of water. In a common evacuator, they are carried wherever it goes, first from the bladder to the bulb, and then, when it is reversed, back to the bladder, a part only falling into the receiver at each aspiration. As we may fairly assume that a surgeon would not deliberately inject foreign bodies into a patient's bladder, there must be

* The specific gravity of hard coal is 1.575. That of a urate calculus is 1.540, and of a mulberry calculus, 1.262.

something wrong in a system which obliges him to do this, and makes it necessary to aspirate the same *débris* twenty times over in order to remove it. In short, the apparatus as commonly arranged is still a defective one, and needs some special contrivance to assist the action of gravity in securing the *débris*.

Surgeons have long felt this. The use of a long elastic tube connected with the catheter has been more than once criticised, and with some reason, on the ground that it might contain fragments which would be returned to the bladder. And, again, in order to shorten by an inch the route from the bladder, a less convenient stop-cock has been substituted for the usual one. But lithotritists should be fully aware of the fact that, whether there is an elastic tube or not, a tenfold greater quantity of fragments is generally driven back out of the bulb itself, and that the difficulty lies almost wholly in that part of the instrument. At each expansion *débris* are drawn from the bladder into the bulb, where they are delayed until, when it is compressed, they are injected back into the bladder. Only a part of them, sometimes only the larger half, the quantity varying in different instruments, settle into the glass receiver. This important fact, so little recognized, should not be accepted without demonstration.

An instrument which Sir Henry Thompson has lately abandoned (Fig. 1) can be made to demonstrate exactly how the currents act upon the fragments in an evacuator which is unprovided with a catheter-trap to prevent them from re-entering the catheter. It is here selected because the peculiar form of this instrument makes it easy to fit a glass tube to it so that we can see what takes place in the interior. Let a piece of glass tube an inch in diameter be inserted at the joint J, J, between the bulb B and the catheter, to show what passes with the current from one to the other in either direction. If the end of the catheter be now placed in a suitable vessel of water containing fragments of coal of different sizes, while the bulb is alternately compressed and allowed to dilate, a continued stream of fragments will be seen rising from the vessel into the bulb, and then returning to the vessel as they inevitably do to the bladder. The back-flow of *débris* can be still better watched if a glass tube be also substituted for the catheter, as in the figure.

But there is another important fact illustrated by this instrument. Fragments do not always stay in a receiver after they have been deposited there. When the glass receiver R of this evacuator is half filled with fragments, a part of these are easily carried back into the bladder or into the vessel. They are first lifted up from the receiver into the bulb, and then driven out through the catheter. For, though the orifice of this glass receiver is small and protected by a special trap, the current and *débris* pass out of it as well as into it. It could not have been foreseen that fragments would escape from a receptacle apparently so well arranged. But it will be found that in any instrument, if the bulb or catheter directs the current into the glass receiver, whether directly or obliquely, fragments are easily carried out again.

And the general result is little better if, to avoid stir-

ring the fragments which lie in the receiver, the current is directed horizontally over the mouth of it instead of into it. Some of them then pass directly back and forth be-

FIG. 1.

B, bulb; R, receiver; J, J, joint. These two figures represent the same instrument, one intended to demonstrate the fact that all instruments which draw fragments into the bulb, and then drive them out through the catheter, are defective. In Fig. 1, the joint J, J, is inserted between the bulb and the catheter, to show what passes with the current from one to the other in either direction. In Fig. 2, the joint J, J, is inserted between the bulb and the receiver, to show what passes with the current from one to the other in either direction. The receiver R is shown in the position of being half filled with fragments, and the current is shown passing from the receiver into the bulb, and then out through the catheter.

tween the bladder and the bulb, over the receiver, without falling into it. This defect can be shown in an instrument recently employed by Sir Henry at the hospital, at Wykes & Co.,* where the stream from the catheter passes horizontally through an empty chamber into the body of the bulb. As the stream enters it, its velocity is so diminished that fragments fall to the bottom into the receiver, in greater number when the bulb is weak. Many fragments are as usual escaped. But, in order to be safely effected, the chamber forced to be turned back up the current by its size would have to be inconveniently large, its glass frame

* See Fig. 1, Plate 7, 1883.

the floating *débris* entering on one side to settle into the receiver without passing farther. The principle here involved is quite different from that of the evacuator represented in the foregoing figure. This instrument is not unlike one formerly figured in the "*Lancet*,"* but the valve and strainer which there act as a trap have been omitted, and, in consequence, not a few fragments escape back to the bladder.

In Weiss's evacuator, again, some of the fragments which enter the bulb gather in the bottom of it, which is lower than its outlet, and where there is no receiver to collect them. The chief difficulty, however, is not that these fragments stray into the bulb, but that, for want of a trap, they are afterward liable to escape out of it, to the bladder.

This difficulty is not wholly obviated by placing a strainer across the mouth of the bulb to prevent the fragments from entering it, as has been done in some other evacuators. Let me mention in this connection the results of a former experiment. It might be supposed that if the passing fragments were arrested by a flat strainer placed across the current, whether at the orifice of the bulb or elsewhere, they would fall into a glass receiver placed directly below them. But this is not the case. Though a large part fall into it, others collect upon the strainer, and, unless the operator pauses after each aspiration till they have settled quietly into the receiver, they are liable to be carried back by the current, unless it is a very weak one. This has happened, in my own experience, whether the strainer was horizontal, vertical, or oblique. The fragments do not glance from it down into the receiver, but some of them cling to it until the current is reversed, and then go back. To make a strainer act as a trap, the fragments should pass freely beyond it and be intercepted only on their return. They will then be strained away from the bladder and not toward it. It is very desirable that the current should be unobstructed while the bulb is expanding, whether by a strainer or by curves and angles in the tubes. A simple flat strainer, placed anywhere across the whole current, retards it, especially if the urine is flocculent.

I find that the simplest expedient for collecting the fragments so that they will settle undisturbed in a glass receiver is, to admit them into the bulb and prevent their escape from it. After many experiments, I have found nothing more effectual for this purpose than a straight cylinder with perforated walls, which is practically a prolongation of the catheter into the bulb. The water, after bringing the fragments from the bladder, is strained as it returns. To the open end of this perforated cylinder a valve might be attached; either a ball-valve moving loosely,† which is less liable to obstruction than a valve with a hinge, or, still better, at the same point half an inch of cotton tube, which opens, allowing the fragments to pass up through it, and collapses with the reversed current, cutting off their retreat, the water, as it returns, passing back through the perforated walls. In operating with this arrangement I have found it to work perfectly, but a valve is not necessary, and the apparatus is more simple without it.‡

The evacuator described below is more simple in construction, and aspirates more perfectly than any I have used. It is shown in Fig. 2, and is a compact modification of one

FIG. 2.

The writer's evacuator. It has an elastic bulb, glass receiver, and stop-cocks.

Below, there is a metal brace between the collar of the glass receiver and that of the catheter, to steady the latter. Within the bulb, and open at the end, is a tube-strainer to prevent the return of *débris*. The bulb forms a concentric handle to the catheter.

formerly published in the "*Lancet*"* as "a simplified evacuator," but without the stand of that instrument, which is not essential, and has been omitted because operators seem to prefer to do without it.

The catheter is made to enter a spherical bulb obliquely upward, and is prolonged to the center of the cavity by the tube just referred to, open at its end, and perforated on its sides with numerous holes, which act as a strainer. The catheter, tube, and elastic bulb are in a straight line. This arrangement has the great advantage of *not deflecting the current* and thereby diminishing its force. During aspiration, the current bearing the *débris* is drawn straight from the bladder through the tube into the widest part of the bulb, and the fragments, spreading there, fall toward the receiver. But, when the bulb is compressed, the water returns mostly through the perforations in the side of the tube because their area is collectively larger than the opening at the end of it, and because they are nearer the point at which the water passes out of the bulb. By means of

it opens to allow the water and the *débris* to pass through, works well enough as a substitute for the tube-strainer. The catheter then opens directly into the bulb, and the route is the shortest possible one. But the tube-strainer is much more simple, and the two inches which it adds to the length of the catheter are quite unimportant. In fact, the usual length of the catheter itself might be reduced two inches to shorten the route if desired. For strainers and strainer-traps, see the "*Lancet*," Sept. 24, 1881. As there described, they are used in pairs, one protecting the entrance of the bulb, while the other, furnished with a valve and placed at the head of the catheter, acts as a trap. The former, for reasons already given, is not always advantageous, but an effectual catheter-trap to arrest returning fragments is necessary.

* "*Lancet*," Sept. 24, 1881, Figs. 8 and 11.

* "*Lancet*," Sept. 24, 1881, Fig. 5. † *Ibid.*, Sept. 24, 1881.

‡ A hinged or other valve-strainer at the mouth of the catheter, if

this simple contrivance the water is strained, and the return of fragments is practically prevented. The tube-strainer can be removed, cleaned, and replaced in a moment, and this is an advantage when there is much mucus, coagulum, or shreddy material in the urine, by which the holes of any strainer may be partly obstructed. Even then this tube continues to work well, but it is better to pass a brush over it if mucus adheres to it. It can be examined as often as the receiver is emptied. After the water has once been changed, less mucus will be found.

The action of the perforated tube meets all requirements. In fact, if the catheter is prolonged into the bulb by a tube which has no perforations in its sides, the instrument will perform very fairly. Such a tube might be fastened permanently in the bulb, but the apparatus can be kept cleaner if there is a joint through which it can be removed. The cavity of the bulb can not be made too accessible.

This arrangement has several other advantages.

1. With the trap placed inside the bulb, the instrument is more compact, shorter, and more easily held, and, as the spherical bulb is here placed in a straight line with the catheter, it forms a concentric handle, which enables the surgeon to direct the catheter better than when this handle is placed above it, at an angle with it.

2. The glass receiver is here attached immediately below the bulb, and is easily seen. A glass cylinder shows fragments better than a globe, but is less capacious.

3. It is well known that the bulb in action, especially when placed above the catheter, at an angle with it, communicates an oscillation to it of which some patients complain. By a special device the catheter is here made so steady while the instrument is in use that a separate stand is not wanted. This consists of a brace uniting the metal collar of the catheter with that of the glass receiver, and so steadying it that the catheter no longer feels the movement of the bulb. The conical projection of the bulb at the point where the catheter is attached contributes to the same result.

4. An elastic hose (Fig. 3), which can be quickly connected with the top of the bulb, facilitates the operation. We can then, with a single compression of the bulb, get rid of any air or discolored water, and replace it with clean water without delay, and without uncoupling the catheter. Besides, no matter how the bulb may have been filled at first,* it is better to be able to vary the quantity of water at any moment afterward, and, although without a hose we can add water through a tunnel, we can not as easily withdraw it in the same way. We should be able to regulate the amount of water carefully, not only at the outset, according to the capacity of the particular bladder, but also during the operation. For example, it is sometimes desirable to draw it quickly away to allow for the muscular strain of retching, or to relieve the expulsive efforts of the bladder itself, which sometimes becomes very tense, and ejects water at the side of the catheter, even the large ones. More

* We can quickly fill the evacuator from a pitcher, if we invert the bulb and detach the receiver. The little remaining air can afterward escape through the hose or tunnel.

water is required at first, while fragments are numerous, to separate them and prevent their being wedged in entering the catheter. Later in the operation less water makes it

FIG. 3.
Apparatus belonging to the evacuator but not essential to it, viz., a tunnel and a hose, both of which fit on the top of the bulb, and an extra stop-cock for the evacuating catheter.

easier to find the last fragment, the minimum being reached when the wall of the bladder vibrates against the orifice of the catheter as the bulb expands, painfully if the patient is conscious. It is then important to add water again, just enough to prevent this obstruction and no more. In short, there is no doubt that we can evacuate better by trying a little more or less water from time to time during the operation, and that this can be done more accurately and more readily by means of a hose than in any other way. With one end attached to the bulb, the other can conveniently remain in a vessel placed between the patient's knees, or in any convenient position, or remain unattached till wanted.

The hose may be used or not. For those who prefer a tunnel (Fig. 3), one is furnished with the instrument; as also a second stop-cock (Fig. 3), which I find useful, if attached to the head of the catheter, in keeping the bed-clothes dry when the bulb is to be removed.

This evacuator is made by Codman & Shurtleff, Boston.

Clinical Reports.

BOSTON LYING-IN HOSPITAL.

Reported by J. FOSTER BUSH, M.D.

(SERVING OF DR. WILLIAM L. RICHARDSON.)

ACUTE PERITONEAL STYPTICS.

Mrs. E., primipara, twenty-one years old, during the latter months of pregnancy had severe headache, not worse when propped in spirits on account of the immobility of her husband. No nausea or vomiting. For the last few weeks there was noticeable diminution of urine, and some swelling of the feet.

April 10th. She continued her fast and bed rest, from which she suffered considerably, and on Wednesday night, April 11th, she complained of severe pain in her head and of seeing floating objects. At about 1 a.m., April 12th, she had a convulsion, the

hands and arms were first rigidly fixed, with the fingers and thumbs clenched into the palms; the face soon became cyanotic, and there was frothing at the mouth, with protrusion of the swollen tongue. This was soon followed by convulsive spasms of the whole muscular system, with rolling up of the globes of the eyes, leaving only the sclerotic portion visible, and retraction of the muscles of the mouth producing a sardonic grin.

After an interval of fifteen or twenty minutes, during which she was partially conscious, another convulsion occurred, more severe than the previous one. A German midwife was then procured, who distinctly felt the foetal movements.

But notwithstanding her wonderful knowledge and the medicine she gave, of which vinegar appears to have been the principal ingredient, convulsions became more frequent, the patient in the intervals lying unconscious, with more or less groaning.

The dispensary physician of the district, Dr. C. P. Strong, who had been called in, was present during one of the convulsions, and at once ordered her removal to the Boston Lying-in Hospital.

The twelfth and last convulsion occurred at 1.30 P. M., April 13th, and at 3.30 P. M. she entered the hospital, in a comatose state, tongue and face swollen and cyanotic. There was no œdema of the legs or feet. Pulse 114 and weak. No urine had been passed for twelve hours. Two and a quarter ounces were drawn by a catheter. The urine was high-colored, and contained about one half of one per cent. of albumin, and numerous hyaline and a few granular casts. A vaginal examination showed that the cervix was not wholly taken up, the os admitting the tip of the finger, the head presenting with the occiput left anterior. The patient was etherized; manual dilatation and version were performed by Dr. W. L. Richardson with difficulty, owing to the low attachment of the placenta and tonic contraction of the uterus. Forty-eight minutes were occupied in the dilatation and extraction of the child, still-born, a male, weighing six pounds. There was considerable post-partum hemorrhage. At 6.30 P. M. urine drawn was $\frac{1}{2}$ oz.; at 8.30, $\frac{1}{2}$ oz.; at 12, 1 oz.; after which urine was drawn every four hours, gradually increasing until it reached $6\frac{7}{8}$ oz. in twenty-four hours, and then diminished to the normal amount.

At 8 P. M. one sixth grain nitrate of pilocarpine was given subcutaneously without effect. The same dose was repeated at nine, which produced considerable perspiration and salivation, Cream-tartar water and milk were given *ad libitum*. Poultices of flaxseed and mustard were applied over the kidneys every four hours.

April 14th.—At 1 A. M. one sixth grain nitrate of pilocarpine was given subcutaneously; there was some perspiration. At 3 A. M. she was very restless; large doses of bromide of potassium and chloral failed to quiet her; was then slightly etherized, after which she slept well. At 8 A. M. one sixth grain nitrate of pilocarpine was given, without effect, and the same dose was repeated at 10.30 A. M., with good result. Tr. digitalis, grt. x every four hours, was given. At 10.30 P. M. natural perspiration occurred, lasting five hours.

April 15th.—At 12.45 A. M., forty-eight hours after the first convulsion, she became conscious, smiled, and nodded her head when asked if she had slept well; drank a glass of milk, after which she relapsed into a semi-comatose state, becoming, however, fully conscious at intervals. Poultices omitted. The evening temperature, 103.1° F.; lochia normal; no abdominal tenderness. Intra-uterine carbolized injections were given, and continued twice daily.

April 16th.—Perspires freely. Examination of urine showed albumin trace; no casts. Burns doing well, being dressed with carbolized oil. The patient is fully conscious, and in good spirits.

She thinks her sickness is due to the burns, and still expects to be confined.

April 17th.—Tr. digitalis omitted. Examination of urine: albumin absent. Evening temperature, 105.4° F.; pulse, 130; lochia normal; slight abdominal tenderness. In addition to the intra-uterine injection, a sponge bath was given.

April 18th.—The morning temperature, 100.9° F.; evening, 100.2° F.

Cream-tartar water and the intra-uterine injections omitted. The patient continued to improve, on the 23d sat up, and, while putting on her clothes, for the first time realized her condition.

She was discharged, well, April 28th.

Book Notices.

Hereditary Syphilitic Eruptions of the Skin in Early Life; or, Congenital Syphilo-Dermata. By JAMES STARTIN, Surgeon and Joint Lecturer to St. John's Hospital for Skin Diseases, etc. London: Henry Renshaw, 1882. [Pamphlet.]

In this pamphlet of nineteen pages the various eruptions of the skin from hereditary syphilis are grouped and described, with brief suggestions as to their diagnosis, etiology, treatment, dietetics, and complications, and a contrasted parallel of the stages and symptoms in acquired and inherited syphilis.

The motive of the writer in publishing this production is not apparent; it certainly adds nothing to our knowledge of the subject, while it has not the merit of presenting accepted facts in a clear and intelligible form. The style is slipshod and confused, often to such a degree that the reader is in doubt as to the precise meaning intended to be conveyed.

In the description of the different eruptions characteristic of congenital syphilis, we notice that the writer still clings to the terms "syphilitic eczema," "syphilitic psoriasis," "syphilitic herpes," etc.—a nomenclature which is condemned by its unphilosophical grouping of two diseases essentially distinct in their nature, and one which is fortunately obsolescent.

A few quotations will indicate the looseness and general indefiniteness of the language employed, as well as the unscientific character of the statements. The author says (page 7): "However severe the symptoms and the eruptions may prove, the child, as a rule, is born in perfect health, with a sound, clear skin." The absurdity of declaring that a child with syphilis "is born in perfect health" is evident. Again, he says: "It might be thought that an outbreak occurring a few days after birth would be more likely to recover than that which shows itself in a month or so; but such is not necessarily the case, nor is the child affected materially by the infection of either the mother or father, as might be thought." The information conveyed in this extremely lucid sentence is somewhat negated by the assertion, on the following page, that "in the great majority of instances the disease descends from the father, but this is not absolutely the rule."

Note cliniche ed anatomiche sulla lepra. Per CAMPANA ROBERTO, Professore nella Regia Università di Genova. Con due tavole. Milano: Fratelli Rechiedei, 1881. [Reprint.]

THE clinical observations of the author of this brochure relate to sixteen cases of lepra, which he has divided into four groups—embracing two cases of macular leprosy, five of tubercular leprosy, two of anæsthetic leprosy, and seven of mixed leprosy, in which latter the characteristics of the three forms generally recognized were more or less blended. He gives his

observations of four of these cases at some length and in detail, describing the symptomatology and the differential features of the several varieties of leprosy. In one of the cases he had an opportunity of making a post-mortem examination, and his anatomico-pathological investigations were conducted systematically and carefully, and are recorded with a minuteness of detail which leaves little to be desired in the way of completeness, as they extended to almost every organ and tissue of the body.

He enters somewhat exhaustively into the treatment of this affection, describing the drugs and methods of treatment which have been tried with more or less success by others. In this part of the work we find nothing essentially new, except possibly the employment of chrysarobin (chrysophanic acid) in the local treatment of certain cutaneous lesions of leprosy.

The histologico-pathological changes in the arteries, nerves, and other tissues, revealed by microscopic analysis, are admirably depicted in two fine lithographic plates.

BOOKS AND PAMPHLETS RECEIVED.

A Treatise on Fractures. By Lewis A. Stimson, B. A., M. D. Professor of Surgical Pathology in the Medical Faculty of the University of the City of New York, etc. With three hundred and sixty illustrations on wood. Philadelphia: Henry C. Lea's Son & Co., 1882. Pp. xvi 33 to 598, inclusive.

Mittheilungen aus der ophthalmiologischen Klinik in Tübingen. Herausgegeben von Dr. Albrecht Nagel, ordentlichem Professor der Augenheilkunde und Vorstände der ophthalmiologischen Klinik an der Universität Tübingen. Erster Band. Tübingen: H. Laupp, 1882. DRAWING ON GELATIN WITH THE CAMERA LUCIDA. M. F. Coomes uses a metallic point for drawing objects with a camera lucida, the drawing being made not on paper, but on a sheet of gelatin. And on a dark ground. The drawing point is always visible, and is used to provide a remedy for the defects of the camera lucida, which is the chief difficulty experienced in drawing from nature by the ordinary method. The drawing is not then rendered transparent to stone. It is questionable whether the advantage gained through the greater distinctness of the drawing point is counterbalanced by the disadvantage of not being able to trace the drawing. As the particular benefit claimed is to be lost when the drawing point that could be retained without great difficulty is rendered transparent, *Royal Microscopical Journal*.

WEED-PACKING IN ANATOMY.—A remedy which may be resorted to when perfectly and suitably constructed, but which may be of great (if indiscriminately used, it will) result in producing a very serious injury to an instrument of precision. *Journal of the Microscopical Society*.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 13, 1883.

DERMATOLOGY IN AMERICA.

It is altogether likely that for many years to come the luster of the late Professor Hebra's fame as the practical founder of modern dermatology will not be dimmed appreciably by the achievements of any other one man. Nor are we unmindful of the steady and effective work that has been accomplished by Sir Erasmus Wilson. But, however prominent an individual may stand out, a less glittering, but on the whole a more substantial, advance in science usually has to be brought about by the concerted labors of the great throng of lesser note. Cutaneous medicine is no exception to this rule; it takes a step forward here, and another there, and its progress, thus insensibly worked out, is among the most solid of the improvements with which the medicine of the present day is to be credited.

Our country may justly claim to have done its full share, and to be doing it still, in this work. It is no more than their due, and a fitting recognition of their painstaking efforts, that the attention of the profession should be called, although not for the first time, to something of what American dermatologists have done. The late Dr. Henry D. Bulkley gave many years of what time he could snatch from the daily duties of a family practitioner to the study of diseases of the skin, and left behind him an invaluable collection of clinical records—data that have since been turned to good account. Dr. Bulkley also gave lectures on dermatology from time to time, and brought out a translation of Cazenave's book. The crowning work of his life, however, was the part he took in founding the New York Dermatological Society, a few years before his death.

This society has flourished from the outset, and its monthly meetings have always brought together a goodly assemblage of men earnest in their devotion to dermatology. But little of its work has taken the form of set essays, and it has steadfastly steered clear of the whirlpool of debates on classification. For the most part, its meetings have been given up to the observation and study of actual cases of skin diseases, and it is doubtful if anywhere else in the world can so many rare cases, puzzling cases, of diseases of the skin be seen in the course of a year as at these meetings.

The American Dermatological Association, although laboring under the disadvantage of meeting but once a year, and necessarily dealing more with formal papers than with clinical work, has yet a most creditable record, as may be learned from its volumes of transactions. Although a younger organization than the New York society, it has accomplished a great deal, mainly in the opportunity it has given for dermatologists from various parts of the country to profit by that wholesome attrition that accompanies the occasional concert of action by men

who are to a great extent strangers each to the other's peculiarities of mind and training.

Shortly after the formation of the New York Dermatological Society, "The American Journal of Syphilography and Dermatology" was established, and its quarterly publication was kept up for four years, with credit to the editor and with profit to the branches of medicine to which it was devoted. At about the time its publication ceased, the issue of "The Archives of Dermatology," another quarterly, was begun. That journal has contained some of the most notable contributions to dermatological literature that have appeared since its establishment. With the number for October, 1882, without having shown the slightest sign of decadence, its existence ended, simultaneously with the appearance of a new monthly journal, "The Journal of Cutaneous and Venereal Diseases," a handsome and promising journal, and one which already gives good grounds, in the few numbers that have been issued, for the hope that it may long continue the good work done by its predecessors. Thus at no time during the past twelve years has dermatology been without its special literary repository in this country, to say nothing of the admirable text-books, colored plates, and photographic portraits that have been produced by American authors.

The didactic and clinical teaching of dermatology has come to be a regular feature in the courses given at our leading colleges, and the interest shown in various private courses of instruction gives evidence that it is not alone among our specialists that the study of diseases of the skin is duly followed, but that the field those diseases afford for general pathological investigation—being, so to speak, an epitome of general pathology—is appreciated by a large proportion of the profession as a body.

Although many of our best-known dermatologists doubtless caught their first enthusiasm in Vienna, they have no more yielded themselves up to the peculiar etiology taught by Hebra than to the opposing views that have been enunciated so persistently and so ably in France. Neither the one nor the other of these disturbing influences has dazzled them, and we may well question if it is not to this independence of thought, this unprejudiced study of the natural history of skin diseases, that we owe the present satisfactory and promising state of dermatology in this country.

THE LATE SIR THOMAS WATSON.

It is safe to say that no physician of modern times has won the hearts of so many of his contemporaries as the revered nonagenarian whose recent decease gives occasion for these remarks. Others have been more admired for their direct contributions to the advancement of our art, but the homage they have received has been that which springs from the intellect rather than from the feelings. Watson's name can not be set down among those of the few men of our period to whom medicine is materially indebted for having aided its progress toward that perfection which we all hope it will ultimately attain to. He made no discovery; he maintained no new theory or practice;

he settled no disputed point. Yet, had he done all these things, and been other than what he was, no such tender words would have been written of him as appeared in our London contemporaries during his last illness. As it grew painfully certain, from week to week, that the end of his life was close at hand, more and more touching were the bulletins. But it was not that the shadow of impending death heightened the love borne him—it needed not that hallowing influence; for, twenty years ago or more, when, although then ripe in years, he was still actively at work, a leniency was shown him that, in this critical age, would not have been accorded to a man for whom admiration rather than esteem had before been felt, on the occasion of his accounting for the steady abatement of the general mortality, notwithstanding the disuse of the lancet, that had figured so prominently in his own practice and teaching, by suggesting that diseases had changed their character. Men saw the weakness of the argument, but it was the honored Watson who had spoken, and captiousness was silenced.

It was not because he was a baronet that his name was held in such reverence, for to that honor he did not attain until he was past seventy-four years of age; it was not for his having been President of the Royal College of Physicians; it was not for the distinction of his having been chosen one of Her Majesty's physicians in ordinary—all these were but coincident results of the career that had already endeared him to every English-speaking practitioner and student of medicine. It was as the lecturer at King's College that men know him far and wide. But few men in Great Britain or in America can have gone through the medical curriculum at any time during the last half-century without reading his matchless lectures on the "Practice of Physic," the charm of which lay not alone in their exquisite style, but in the witness that every page bore of their author's practical acumen, and in the graphic pictures of disease that could not but be taken in and remembered. It was a work that never exacted any exertion on the reader's part, and yet never failed to command his respectful attention. None but a great man can write such a book, and that fact was recognized intuitively by every reader. It does not reflect the medicine of the present day, but none the less it is still a power, and none the less will its way be acknowledged so long as a masterly portrayal of the clinical aspects of disease is appreciated. Sir Thomas Watson, although no longer in the flesh, still lives in its pages, lighting up the dry and formal records of medicine, and teaching us anew the lesson of a long and graceful career.

THE DEARTH OF ANATOMICAL MATERIAL IN PHILADELPHIA.

It is to be hoped that the community which lately unhorsed Buchanan, and broke up his revolting trade in medical diplomas, will lose no time in putting an end to its present treatment of its physicians—that, namely, of requiring them to make bricks without straw; in other words, holding them responsible for ignorance of their art, and yet withholding the only means whereby they may acquire anything approaching an

adequate knowledge of the very corner-stone of that art, the anatomy of the human body.

How many of the mature practitioners who earned their degree in Philadelphia, and who are now scattered over the length and breadth of the land, can patiently mingle with their recollections of alma mater the thought that now, in the city of Horner, of Mütter, of Pancoast, and of Leidy, the demonstrator of anatomy in one of her honored colleges languishes in the grasp of the law, charged with having connived at a systematic course of ruffianly desecration of the sepulchre—all for the want of that decent and seemly provision that every civilized government recognizes the necessity of making for the practical study of anatomy? And yet that is the actual state of things.

Truly, the glory of Philadelphia will have paled when that old-time center of medical teaching shall not only see the accustomed throng of pilgrims diverted to other regions, but shall also be forced to send her own sons beyond her borders for instruction; but that time will tread close upon any lasting obstacle in the way of dissection. Whatever else may be glossed over, no apology will be taken in extenuation of any shortcoming in the means for teaching anatomy.

It is easy to pour obloquy upon the demonstrator in question, to argue that he should not have yielded before what he doubtless considered the inexorable force of circumstances. That is quite true, and his conduct seems wholly indefensible, provided the charges against him are substantiated; but it does not shift the responsibility from the shoulders of those whose business it was to see that no such crushing temptation was thrown in his way. Medicine has nothing to gain, but everything to lose, by covering up unlawful and abhorrent acts committed in her name; but, having resolutely refrained from any such course of action, it can, with all the more vantage, call upon the legislative power to remedy the evil that this man's conduct might, but for his detection, have enabled him to evade in the future as it doubtless has in the past.

The astonishing phase of the matter is, that this thing has occurred at such a late date. We can scarcely suppose that the public provision for the supply of anatomical material at present is grossly different from what it has been in the past, nor can we entertain the idea that a systematic course of grave-robbing has heretofore been followed in Philadelphia, lasting through all the years that that city has been prominent in medical teaching, and only now coming to light. One explanation is offered, indeed, embodying a new feature in "bossism," to the effect that a coroner, who is also interested in a private school of anatomy, makes such use of his power in the disposal of the dead as to hamper the great medical schools, while his own institution suffers no want. That a member of the profession should thus be guilty of strangling the author of his official being, is too monstrous to be credited without more substantial proof than has yet come to light. Whatever may turn out to be the true reason for the humiliating state of things that now exists, we feel confident that a remedy will soon be enforced, for Philadelphia can not afford to let her prestige in medical teaching go by default.

THE PROPOSED NEW FRENCH DEGREE.

THE project being under consideration in France of creating a grade superior to that of doctor of medicine—that, namely, of doctor of the medical sciences (*docteur ès sciences médicales*)—the Minister of Public Instruction has issued a circular of inquiry to the rectors of the various colleges, asking for their views as to the probable utility of the measure, and as to the proper requirements to be exacted of candidates for the proposed new degree.

Some uncertainty seems to be felt among the profession in France as to what effect the adoption of the scheme may have upon the status of practitioners. It is hinted that the professors and the *agregés* may find it the means of abridging the lofty height to which they now tower above the rank and file, since a sort of gradation may be established between the two by the creation of an intermediate dignity.

It is feared, too, that abuse may readily creep in by reason of the degree being conferred upon some whose only claim to any such stamp of distinction will be found to have been based on work of no noteworthy merit. Moreover, it is obvious that in the general run of instances the achievement of that amount of eminence, due to individual contributions to the advancement of medicine, that should really entitle one to so marked a recognition as is implied in a degree of this sort, falls to the lot of workers in the special branches of medicine, more especially the elementary branches. Now, suppose a man to have reached this pitch of eminence, in physiology, for example; the absurdity of dubbing him doctor of the medical sciences on that account is extreme, for in regard to much that goes to make up the sum of what we call the medical sciences he is quite likely to be behind the ordinary practitioner.

It is evident that only the general practitioner, or at least the student of general medicine, can attain to such a height of excellence in the whole range of the medical sciences as to warrant the title in question being conferred upon him; and how many such men are to be met with in a generation? The degree would be given to such a man, if at all, in conformity with the general voice of the profession, tacitly if not avowedly. Trousseau might, perhaps, have won such a suffrage, but it would be given to very few, we fancy, to secure that amount of homage from their associates, short of their practical superannuation, at all events. The minister's circular, indeed, takes account of tests of far less weight than any that we have mentioned, even entertaining the idea that it may be thought wise to confer the degree on all who have been hospital internes. It can scarcely be doubted that such a paltry consideration as that would utterly defeat the intention that seems to underlie the project.

The essential idea of the scheme, that of setting the seal of public recognition on a career of more than ordinary merit, seems to us a good one, but the proposed title does not strike us as answering the purpose. Perhaps it would be better to make the doctorate the higher grade, giving a lesser degree at graduation from a medical school—that of bachelor of medicine, for example.

THE NEW SURGEON-GENERAL OF THE STATE.

IN selecting Dr. Joseph D. Bryant, Professor of Anatomy in the Bellevue Hospital Medical College, for the position of Surgeon-General on his staff, Governor Cleveland gives an earnest that, in so far as his medical appointments may be concerned, care is likely to be taken that a just discrimination as to professional standing and fitness shall not fail to be exercised. In that respect his course stands out in marked contrast with that of his immediate predecessor.

It is so seldom that the profession have reason to feel satisfied with political appointments from their ranks that we feel inclined to emphasize the expression of our gratification at the judicious choice that has been made in this instance. Dr. Bryant's position as an attractive and successful teacher of anatomy, and as an esteemed practitioner, impels us to say that the Governor honors not so much the appointee as the office. Short of an outbreak of war—which God forbid—the Surgeon-General is, indeed, not likely to have forced upon him any actual duties more trying than that of a dignified bearing, yet we trust that the Governor will not hesitate to require his action, in an advisory capacity, not only in regard to medical appointments in the National Guard, but also with reference to such other selections of medical officials as may have to be made during his incumbency. In no way could the interests of the State be better served by the office.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

A STATED meeting was held November 28, 1882, Dr. T. M. MARKOE, President, in the chair.

DR. J. C. HUTCHISON read a paper on

SUBCUTANEOUS OSTEOTOMY BELOW THE TROCHANTER.—Dr. H. B. SANDS referred to a case, occurring in an adult, in which he performed Adams's operation. The deformity was anchylosis at an angle of 110° , the result of articular rheumatism. He divided the neck of the femur, and the wound healed by adhesion under a simple dressing. The man was kept in bed for six weeks, with the view to obtaining bony anchylosis in a straight position; but a false joint formed, and when he left the hospital, two months after the operation, the limb was shortened one fourth of an inch. A year and a half after the operation the limb was shortened three fourths of an inch, and still there was a movable joint, but the deformity was entirely relieved. As in Dr. Hutchison's case, it was necessary to divide some of the tendons in order to bring the limb into the proper position. The final result was that the patient was able, without a cane, to walk with only a slight limp, and with a cane no limp could be detected.

DR. C. T. POORE remarked that he had not seen reported cases in which motion remained after section high up, except in Dr. Sands's and Dr. Sayre's cases, and one published by Dr. David L. Rogers, in 1830, in which motion existed three and a half years after the operation. Barwell, of London, had reported a case in which he performed double section high up, adopting Gant's method, and the patient died on the forty-seventh day from bed-sores. The case was one of anchylosis from double strumous hip-joint disease. He thought that osteotomy, as performed by any of the usual methods, could hardly be called subcutaneous.

DR. HUTCHISON thought that Gant's operation was subcu-

taneous, as the skin was drawn well to one side before the puncture was made.

Dr. A. C. Post had performed osteotomy at the upper part of the femur in two cases. In the first, performed many years ago at the New York Hospital, he divided the bone just below the lesser trochanter by an open section. The limb became gangrenous, and the patient died. At the autopsy it was found that the great vessels had become caught over the upper fragment of bone, and in that manner the circulation in the limb had been destroyed.

The other case was one in which there had been double morbus osseus. On a former occasion he had excised the head of the femur upon one side. The head of the femur upon the opposite side subsequently became diseased, and ankylosis occurred while extension was being used. As there was profuse deep-seated suppuration around the bone, Dr. Post commenced the operation with the view of excising the head of the femur. But finding that the head was inseparably connected with the acetabulum, he divided the bone with a saw just below the trochanter minor; and, as the limb was considerably longer than its fellow, having divided the bone, he removed a piece, so as to make the two extremities nearly of the same length. Ankylosis took place after the operation; the limb was in the straight position, and was useful.

Dr. HUTCHINSON said that one of the most interesting cases he had met with, among those reported, was Mr. Lund's, of Manchester. There was ankylosis at both hip joints, the result of rheumatic arthritis. The patient was unable to sit; could only stand or lie down. Mr. Lund performed Adams's operation, and succeeded in getting false joints, after which the patient was able to sit and walk very comfortably. The result was attributed largely to a suggestion made by Mr. Adams—that the patient draw up the limb, while the weight and pulley were attached, several times a day, for the purpose of preventing union of the bone.

Dr. GEORGE A. PETERS directed attention to another method of correcting the deformity—namely, fracture of the bone, which he had regarded as safer than dividing the bone through an open wound. One difficulty in applying the method had been to produce the fracture at the exact point desired. This he thought had been overcome by the osteoclast devised by Dr. Fayette Taylor, a complete description of which had been published in the "New York Medical Journal." In the case reported, Dr. Taylor fractured the femur just below the trochanter, straightened the limb, and Dr. Peters took charge of the case during its progress. The result was complete union, with the limb in good position. At the time the operation was performed, it seemed to him to be a much safer procedure than section of the bone, and he should be inclined to adopt it.

Dr. C. K. BRIDGON referred to the case of a girl, eighteen years of age, who entered the Presbyterian Hospital with ankylosis at the hip joint, and ankylosis of the right hand. As he recollected, the heel was five inches from the floor. While making an examination under ether, he accidentally fractured the bone about four inches below the trochanter minor. The limb was placed in the straight position, a fixed apparatus was applied, and union took place. The result was very good. The shortening was very much diminished.

Dr. SANDS said he was unable fully to understand how any instrument could determine the point of fracture within half an inch. If it was desired to fracture the bone where it was thickened, as the result of inflammation, he should fear that it would give way at its weakest point. In his case the bone was excessively firm, and twenty-five minutes were occupied in dividing it. He was quite certain that the application of a force sufficient to cause fracture would have broken it at some lower point.

With regard to the relative safety of osteotomy and fracture, he doubted if there had been sufficient experience to enable us to compare the two operations. Certainly osteotomy had been remarkably successful, and he should appreciate it as such. If enough was applied to cause fracture, the large blood-vessels might occasionally be injured.

Dr. PETERS said that when Dr. Taylor first proposed the operation he objected to it for the same reasons which had just been given by Dr. Sands. But when he saw the apparatus, and especially after seeing it used, he believed that there was an almost absolute certainty that the bone would not be fractured except at the exact point selected.

The PRESIDENT suggested that fracture at a precise point, although he had not tried it, in the class of cases under consideration, might be secured by first using Brainard's drills, and afterward the osteoclast. He had used the drills in several cases of vicious union with satisfactory results.

Another suggestion was with reference to the accident which occurred in Dr. Post's case. Perhaps the danger had been somewhat overlooked of the sharp edge of bone wounding or abrading important vessels. This accident had occurred to him, and Dr. Peters would recall the case. After dividing the bone in the middle position of the femur, with great difficulty, with a chisel, in a case in which the bone exhibited a deformity nearly at a right angle after necrosis, he had the misfortune to rupture the femoral artery in making extension for the purpose of bringing the fragments of bone into proper position. The result was that the limb was destroyed, although the patient's life was saved by amputation high up. On examination of the limb after amputation, it was found that the artery had become attached to the posterior surface of the bone as the result of long-continued inflammation in connection with the necrosis, and, of course, when the bone was straightened, the artery was torn across. He thought it was one of the points to be borne in mind in all operative procedures in this class of cases.

LITHOTOMY THROUGH THE PERINEUM. Dr. GEORGE A. PETERS reported a case as follows: On the 6th of November he removed a stone from the bladder of a boy ten years of age, who had suffered from symptoms of vesical calculus for five years. On examining the bladder with a Thompson's searcher, a stone was readily detected, and it was estimated to be of large size, hard and rough. The patient was prepared for the operation, and, after he was placed upon the table, bimanual examination, with one finger in the rectum, and pressure made above the pubes, detected a stone in the bladder which was then estimated to be over an inch in length. Appreciating the fact that he had to deal with a large calculus, Dr. Peters determined to perform the median operation, with some modification, and, through the opening thus made in the urethra, to crush and remove the fragments. The modification consisted in making the incision through the skin, and to some distance through the soft parts, and then introducing the knife in the usual manner, touching the groove in the staff and dividing the urethra. A pair of forceps was then introduced into the bladder, with the expectation of being able to crush the stone, but it was found to be at least one and three quarter inches in diameter, and the instrument too weak to break it. Considerable difficulty was then experienced in removing the forceps from the stone, as the bladder was empty and had contracted firmly. The forceps being removed, a short incision was made in the bladder, and Dr. Weiss, of London, for crushing stone in the female bladder—was introduced; but, after the calculus was grasped, it proved to be so large that the instrument could not be locked.

Highwick's large Lithotrite was then introduced, the stone was seized and crushed several times, several of the large fragments were removed with the forceps, and the operation was completed.

with the scoop, passing it over every portion of the bladder. On introducing the finger, he found that the irritation produced by the operation had caused hour-glass contraction, so that there were some fragments shut up in the upper part of the bladder. Finally the bladder was emptied completely. The fragments and detritus collected weighed four hundred and seventy grains. During the subsequent history of the case nothing of special importance occurred, except high temperature— 105° F. during a part of the first twenty-four hours. But that readily yielded, and on the sixth day the boy began to pass water through the penis, and on the twelfth day the urine was passed entirely in the normal manner. From that date the case had progressed favorably.

Dr. Peters suggested that, should he again be called upon to operate in a similar case—a young person's bladder with a large stone—he should perform litholapaxy through the perineum in the following manner: Make an incision in the perineum, enter the urethra a little farther forward than in ordinary median lithotomy; and by an incision only large enough to admit a lithotrite, and through that opening crush the stone and extract the fragments, as in ordinary rapid lithotripsy with Bigelow's apparatus.

In connection with the report of this case Dr. Peters exhibited

AN APPARATUS FOR SECURING GOOD POSITION IN ALL OPERATIONS ON THE PERINEUM, THE BLADDER, THE VAGINA, OR THE RECTUM.—It had been brought from London by Dr. T. A. Emmet, and consisted of two padded rings or bands to encircle the legs just below the knees. To one ring was attached a steel rod, to the other a barrel which received the rod. The rod could be secured at any point by means of a thumb-screw passing through the wall of the barrel, and thus permitted any degree of extension required (consequently, separation of the knees, and placing the perineum on the stretch). To the inside of one ring was attached a strap which was to pass around the patient's neck and be held fast with a buckle at the inner side of the opposite ring. With this strap the elevation of the limbs could be regulated. [A more complete description, with illustration, can be found in the "Medical Record" for December 9, 1882.]

CANCER OF THE THYROID BODY.—Dr. A. G. GERSTER presented a specimen removed last August from a patient sixty-two years of age. It had the following history: A woman, very fleshy, had carried a goitre for several years. During the last five years she had suffered from periodical attacks of dyspnoea, which passed off without special treatment. For about four months before he saw the patient the dyspnoea had been almost constant, and her general symptoms had increased in severity to an alarming extent. On examination, he found in the median line of the neck a tumor about the size of an orange, and hard. It moved up and down with deglutition. The dyspnoea was so marked that the wheezing inspirations of the patient could be heard in the second and third rooms distant. Her face and lips were slightly cyanosed, and she was obliged to maintain the upright position. There was evidence of fatty heart, and of a certain amount of pulmonary emphysema, apparently induced by the tumor. Several methods of treatment had been employed before he saw the case, and last some sort of injections into the tumor by an irregular practitioner. From that date the alarming condition took its origin. The tumor was attached to the anterior surface of the trachea, and it was evident that tracheotomy, so certainly indicated, could be performed only with great difficulty. One of two ways could be adopted in performing tracheotomy: either cut directly through the tumor, or remove the tumor first, and afterward open the trachea. He was unable at that time to decide which he would adopt. The pa-

tient, however, declined any operative interference, and went away. Not long afterward Dr. Post saw the patient, and proposed tracheotomy, but the proposition was declined. Finally Dr. Gerster was called, and was asked to resort to whatever surgical procedure was necessary. Not having a cannula of the proper size, he was obliged to extemporize one as follows: Three inches and three quarters of the curved end of a tin catheter, of No. 13 English caliber, were cut off for a cannula. A suitable piece of sheet brass was perforated in the middle for the admittance of the cannula, which latter also received two lateral holes near the end fitted to the plate. Two wire loops, placed near the large aperture of the plate, served to hold the cannula and the plate together by means of a wire pin thrust through the loops and the cannula.

Although the woman had fatty heart, and her general condition was very bad, he preferred to use chloroform, on account of the threatening lung complication. The anæsthetic was administered without accident. An incision, extending from the chin to the jugular fossa, was made in the median line and down to the capsule of the tumor. This did not give sufficient space, and a second incision was made, at a right angle with the first, at about the middle of the neck, and extending from the anterior margin of one sterno-cleido-mastoid muscle to the first incision. Beginning at the lower border of the tumor, he proceeded to enucleate the growth, and soon discovered that it was attached to the anterior surface of the trachea. Whenever he lifted the tumor the trachea was so much compressed as to prevent the entrance of air into the lungs. By means of a blunt instrument he therefore dissected the tumor off, and then found that the tracheal rings from the first to the fifth had been involved in the disease. After the trachea had been laid bare there was no diminution in the severity of the dyspnoea. An incision was made through the tracheal rings, and the tube was introduced. No unfavorable symptoms followed. The patient recovered rapidly from the anæsthetic, and took food shortly after the operation. During the first twenty-four hours she had slight fever. In the afternoon of the second day she had an attack of threatening collapse, for which stimulants were given, and she rallied. It was ordered that the stimulant be continued, and increased should threatening symptoms again appear. Either through failure to give sufficiently explicit directions, or lack of understanding on the part of the attendants, stimulants were given to the extent of producing acute alcoholic intoxication, and on the evening of the third day she was a maniacal drunken person, and in the drunken fit died in collapse.

Dr. Gerster reported the case for its interest in the manner of death as much as for the interest in the tumor itself. The tumor had been examined microscopically, and determined to be a cancer. The prognosis in malignant growths of the thyroid gland was very unfavorable. In a recent number of Langenbeck's "Archiv" a synopsis had been given of the published cases, and it had been found that most of the patients perished very shortly after an operation, whether for removal of the body or for tracheotomy necessitated by the great difficulty of breathing. But, despite the bad prognosis, he thought the surgeon was justified in attempting to give these patients relief.

The hæmorrhage at the operation was very slight, as every portion of connective tissue was divided between two ligatures.

In reply to questions, Dr. Gerster remarked that the tracheal rings could not be recognized by sensation as the knife passed through the tissues, and yet the trachea maintained its usual appearance after the tumor had been removed from its anterior surface. In most of these cases similar tumors had existed in the mediastinum, and the tracheotomy was therefore performed to obviate death from sudden development of subsequent attacks of dyspnoea.

Reports on the Progress of Medicine.

QUARTERLY REPORT ON OPHTHALMOLOGY AND OTOTOLOGY.

No. XII.

By CHARLES STEEDMAN BULL, A.M., M.D.

LECTURER ON OPHTHALMOLOGY AND OTOTOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, AND TO THE NURSERY AND CHILD'S HOSPITAL.

(Concluded from page 26.)

A NEW REGISTERING PERIMETER.—Priestley Smith C. Ophth. Rev., Nov., 1882) has devised a new perimeter, which he describes as follows: The base of the instrument is a strong wooden stand, 19 inches long by 8 inches wide. It contains a drawer, in which lie the charts, squares of paper for test-objects, and colored pencils for outlining the field. At one end of the base is a short metal support carrying a wooden pillar, which terminates above in a round knob. The patient rests his face lightly against the pillar, so that his eye stands vertically over the knob, and about an inch and a half above it. At the other end of the base is a strong metal column, bearing the movable portions of the perimeter, viz., the axis carrying the quadrant, hand-wheel and pricker, and the chart-holder. The quadrant is a flat slip of brass, presenting its edge to the eye under examination, and engraved on its two sides in intervals of five degrees; the figures are thus hidden from the patient, but visible to the operator. The test-object, a square of paper changeable at pleasure, is held in a little clip which slides on the quadrant; the latter is notched on its outer edge, so that the test-object is readily moved along by ten degrees or five degrees at a time. The radius of the inner edge of the quadrant is ten inches. The revolving axis which carries the quadrant has fixed to its other end a wooden disc or hand-wheel eight inches in diameter, by means of which it is rotated; this wheel is weighted in such a way as to counterbalance the weight of the arc; the latter, therefore, travels smoothly round the whole circle, and remains at any point at which it may be placed. On the posterior surface of the hand-wheel is the pricker. This is a pointed steel pencil, which slides in a brass plate in the meridian corresponding to the quadrant of the perimeter. The brass plate is graduated from 0° to 90°, like the quadrant. The position of the pencil is altered by the finger and thumb of the operator acting on buttons near the edge of the hand-wheel. Behind the hand-wheel is the chart holder, hinged at the bottom and kept in position by a spring-catch; when the catch is raised by the finger the chart-holder falls backward, so that the chart may be inspected or a new one introduced. The chart is thus held very near to the point of the pricker, and is easily brought into contact with it by the thumb of the operator. When the pricker is drawn out to 90° on the scale, it travels over the outermost circle of the chart; when it is pushed down to 0°, it stands in the axis of the instrument and corresponds to the center of the chart.

POWDERED BORIC ACID IN THE TREATMENT OF PURULENT CONJUNCTIVITIS.—Ferguson ("Ophth. Rev.," Nov., 1882) suggests the application of finely powdered boric acid to the conjunctiva in purulent conjunctivitis. He has found that it checks the discharge completely for a period varying from two to twelve hours, and in the milder cases the first application is sufficient to stop the discharge altogether. When the discharge reappears, it is usually less in amount and more watery in character, and a very few applications of the powder stop it entirely. The con-

junctiva is then red and succulent, but dry, and, if touched two or three times with a solution of silver nitrate, it rapidly returns to its normal state.

NYSTAGMUS AND HEMERALOPIA IN MINERS.—DUBREUIL (Arch. d'oculistique," Sept.-Oct., 1882) comes to the following conclusions as regards the etiology and prognosis of nystagmus and hemeralopia occurring in miners: 1. The nystagmus of miners is a simple paresis of the levator muscles and nerves of the eye, produced by fatigue in these levators as a consequence of work in veins but slightly elevated and in low galleries; and is independent of a central lesion of the nervous system, as well as of any error of refraction. The general atony, anæmia, and faulty illumination are secondarily important factors, but not essential to the production of nystagmus in miners. 2. There exists in miners a hemeralopia closely connected with the nystagmus, but which may exist independently of this affection. 3. The nystagmus of miners is a curable disease, and should not be considered as a reason for exemption from military service.

CERTAIN COMPLICATIONS FOLLOWING THE OPERATION FOR THE EXTRACTION OF CATARACT, AND THE MEANS OF PREVENTING OR REMEDYING THEM.—ABADIE (Arch. d'oculistique," Sept.-Oct., 1882) begins by sounding the praises of strict antiseptic surgery, but admits that, in spite of all these precautions, there occur from time to time cases of suppurative iridochoroiditis after extraction of cataract. These secondary complications Abadie regards as due, in the immense majority of cases, to the inoculation of septic substances in the corneal wound. The influence of these germs deposited in the wound far outweighs in importance any diathetic influence in the causation of inflammation. When the inflammation develops rapidly, within twenty-four hours after the operation, it is generally very violent and very grave, and, in spite of all antiphlogistic treatment, the eye is usually lost by suppuration. Convinced that the cause is infection of the wound, Abadie now uses disinfectants from the beginning, in place of antiphlogistics. As soon as the danger threatens he removes the bandage, separates the lips of the corneal wound with a probe, and evacuates the contents of the anterior chamber, if necessary, by slight pressure on the eyeball. He then introduces into the anterior chamber the spray from a vaporizing machine filled with a saturated solution of boracic acid, and thus irrigates completely and effectually the anterior chamber. Then during the day every fifteen minutes, and several times during the night, a spray of the same strength is directed upon the eye so as to cleanse completely the conjunctival surface. Every four hours a collyrium of eserine is to be instilled. At the end of twenty-four hours the chemosis is noticeably diminished, the pain is less, and all the symptoms are more favorable. This treatment is to be kept up as long as may be deemed necessary. When the inflammatory action threatens to be very violent, Abadie cauterizes the entire extent of the corneal wound with the galvano-cautery, the platinum wire being heated to a white heat; and he has seen the cornea on the following day become transparent, the aqueous humor regain its limpidity, and the morbid process arrested completely.

OTOLOGY.

HÆMORRHAGIC INFLAMMATION OF THE LABYRINTH IN CHILDREN.—Lucæ ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," lxxxviii, 3) states that if in a previously normal ear complete deafness suddenly appears, we must assume that there has occurred a sudden hæmorrhage into the labyrinth. When this occurs in children the deafness is, almost without exception, bilateral, and more or less complete; and coming as it does usually at a very early age, the result is almost certain to be deaf-mutism. In one case which he reports there were two stages distinguishable in the disease: one short, which, under the form of epidemic cerebro-spinal meningitis, is about ended on the tenth day; and a second longer, which, with a reappearance of the meningeal symptoms, ended in six weeks in death. The close of the first period was marked by the sudden deafness, which was bilateral and complete, and remained so until death. The deafness is not accompanied by vertigo. At the autopsy of this case, in detaching the dura from the petrous bone there was seen on both sides a moderately thick, red, vascular, cord-like prolongation from the dura, which entered the petrous bone beneath the superior semicircular canal. When this was removed, its place of entrance was found to be a deep, red, triangular opening. Lucæ concluded that this was the channel by which the inflammation was propagated from the brain to the labyrinth, and that in this propagation the bony structure surrounding the semicircular canals plays an important part. An osteomyelitis first arises, then the vessels become inflamed, and finally a hæmorrhagic inflammation in the semicircular canals is produced, in which it is still uncertain whether the inflammation or the hæmorrhage is the first step. This bony structure in young children is extremely thin. If the dura covering the petrous bone be regarded as its periosteum, which acts as conductor for the nutritive fluid coming from the middle meningeal artery and its various branches to the pyramid, it will be seen, on careful examination, that of these arterial branches the arteria subarcuata is the one upon which the growth of the bony tissue surrounding the semicircular canals depends. It is known that in new-born infants the two vertical canals lie almost uncovered, and that the vascular cord from the dura is here very large, and its point of entrance is very wide, while as years go on, both become smaller from de-

posit of bone around them. This may explain why diseases of the cranial cavity and middle ear in young children so often lead to great disturbances of nutrition of the pyramid and labyrinth. To this circumstance must be ascribed the great vulnerability of the labyrinth in very young children. The great danger of all is the threatening deaf-mutism, because the exciting cause for these destructive changes in the labyrinth occurs at a period when the child either has not yet begun to speak, or else when the command of the faculty of speech is still very slight.

NEW AUDIOMETER FOR APPRECIATING AUDITORY SENSIBILITY.

—Lacharrière ("Ann. des mal. de l'oreille," etc., July, 1882) describes a new audiometer for determining the degree of auditory sensibility. It consists, 1, of a microphone for giving appreciation of the noise, and set in motion by two small piles of chloride of silver; 2, of a tuning-fork, caused to vibrate by a battery of four piles of manganese; 3, of a telephone for transmitting to the ear noises and sounds; 4, of a rheostat for determining the number of ohms or electric units introduced into the circuit; 5, of the principal induction-coil, which is traversed by the currents from both sources of electricity, which is Boudet's. The tuning-fork is made to vibrate by four elements of binoxide of manganese contained in the bottom of the box. The current penetrates the tuning-fork on one side by the heel of the instrument, which receives the wire of the negative pole, and from the other side by an induction-coil placed at its ends. The innermost induction-coil is connected with the pile by the "manette," and gives off a wire, which, by the aid of a regulating button, connects it with the platinum wire bound to the end of the tuning-fork, and serves as interrupter. The outermost induction-coil is connected on one side with the rheostat, and on the other with Boudet's induction-coil.

AUDIOMETERS.—Baratoux ("Rev. mens. d'otol.," Aug., 1882) describes a modification of Boudet's audiometer, which he thinks is an improvement. He preserves the rheostat and telephone in place, but suppresses the microphone and watch. In the place of the latter he has introduced an electric tuning-fork with a single coil. This tuning-fork is attached at one end to the pile, and at the other to a Boudet's coil. By means of the formula given by Boudet, he can measure the auditory acuity in ohms. To do this, it is necessary to first measure the resistance of all the apparatus employed. He employs the pile of Calland-Trouvé.

BOILER-MAKER'S DEAFNESS AND HEARING IN A NOISE.—Dr. Holt ("Trans. of the Am. Ophth. Soc.," iii, 1, 1882) has examined the hearing and ears of a large number of boiler-makers. He found that several of these men could hear the tick of a watch when pressed against the auricle, when they could not hear it from the mastoid or the temple. When placed vibrating in the center of the teeth or vertex, the tuning-fork was invariably heard better in the poorer ear. The length of time the tuning-fork was heard by bone conduction indicated that the deafness was not due wholly to the effects of the concussions upon the nerves, but that it was principally due to the effects of the occupation upon the conducting apparatus of the ear, since they heard the tuning-fork, when placed vibrating in the center of the teeth, as long as or longer than the normal ear, and always longer in the deafer ear for aerial sounds. The more Holt examined these men, the more he was impressed with the idea that the impaired hearing was due much more to the condition of the conducting apparatus than to an impairment of the central perceptive apparatus of the ear, and also that there was a direct bone or tissue conduction of sound to the nerve. In all, the membrana tympani showed about the same changes that are observed to have taken place in chronic catarrhal otitis media. The naso-pharynx was invariably in a catarrhal condi-

tion. The Eustachian tube was patent in most of the cases. He thinks that those patients who claim that they can hear better in a noise are inexact in their observations, and labor under a misapprehension of facts. In reviewing the results of the examination of the men who are employed in making steam-boilers, Holt finds that all thus engaged become more or less deaf, the degree and length of time elapsing before this occurs depending somewhat upon the tendency of the middle ear to take on catarrhal inflammation. The deafness and condition in which the organ of hearing is found does not differ materially from that of chronic catarrhal otitis media, since it is produced by a similar cause, and is due much more to a defect in the conducting apparatus of the ear than to the perceptive part of the same organ, the exciting cause of the deafness being traceable to the constant agitation of the joints of the ossicles, thereby exciting inflammation of these structures, and producing more or less ankylosis of them, particularly of the stapes.

TREATMENT OF AURAL POLYPL.—Knapp ("Trans. of the Am. Ophth. Soc.," iii, 1, 1882) takes occasion to warn against repeated cauterizations, and expresses a decided opinion in favor of the alcohol treatment. He recommends that granulations with a broad basis be allowed to grow until they have become pedunculated. He prefers the old method of avulsion, as being both expeditious and efficient.

BILATERAL ABSENCE OF THE LABYRINTH IN A DEAF-MUTE.—Moos and Steinbrügge ("Ztschr. f. Ohrenheilk.," xi, 4) found that the labyrinth was absent on both sides. On the right side there was no space corresponding to the vestibule, nor was there any sign of a cavity of a semicircular canal or of an ampulla. In place of the vestibule was a mass of fat-globules and finely meshed connective-tissue fibers. The canals for the passage of the vestibular nerves were, however, present, as well as the nerves themselves. There was no trace of the cochlea. On the left side almost exactly similar conditions existed; there was not a trace of semicircular canals, ampulla, or cochlea. On examining the auditory nerves, some of the fibers were normal, but others were altered and pushed aside by connective-tissue fibers, and had lost their medullary sheath either entirely or in part. Varicosities of varying size were very numerous in the course of the nerve fibers, so that in many places they looked like a string of pearls. In between the fibers were occasionally seen groups of rounded hyaline globules. The entire process was atrophic and pathological, the atrophy being that from inactivity or disuse. It is to be regarded as another proof of the correctness of the view that the different parts of the ear are developed independently.

ACUTE DEGENERATION OF THE AUDITORY NERVES IN PACHY-MENINGITIS.—In examining the skull and ears of a patient who died from hemorrhagic pachymeningitis complicated with pyæmia, Moos and Steinbrügge ("Ztschr. f. Ohrenheilk.," xi, 4) found changes in the auditory nerve and right internal auditory artery. The auditory nerves had both undergone degeneration of their trunks in the labyrinth, the cause of this being the very considerable subdural and interfascicular extravasations of blood, and the thrombotic changes in the course of the internal auditory artery. The latter probably occurred only a short time before death, and the structure of the thrombus did not furnish any grounds for assuming its pyæmic origin. The hæmorrhage into the nerve caused a laceration of a large number of nerve fibers, which, deprived of their nutrition, soon degenerated. The entire process was very acute during the last days of life, for the peripheral nerves in the labyrinth remained intact, in spite of the degeneration in the trunk of the auditory nerve. The degenerative process, moreover, was limited rather to the central portion of the nerve trunk, while the more superficial nerve fibers remained normal.

THE SENSE OF DIZZINESS IN DEAF-MUTES.—JAMES C. AID. *Jour. of Otol.*, Oct., 1882) has made some interesting observations upon the sense of dizziness in deaf-mutes. He assumed that among the inmates of deaf-mute asylums there must be a considerable number in whom either the labyrinths or the auditory nerves in their totality have been destroyed by the same causes that produced the deafness. If the semicircular canals be really the starting-points of the sensation of dizziness, we ought to find a certain proportion of deaf-mutes who are completely insusceptible of that affection, and others who enjoy immunity in a less complete degree. His observations were made upon 519 deaf-mutes, of whom 186 are reported as totally insusceptible of being made dizzy by whirling rapidly round with the head in any position whatever, and 184 are set down as dizzy in a very slight degree. The simplest way of testing the matter was by active spinning about on the feet with the head successively upright, bent forward, and inclined on one shoulder, the eyes being closed, to eliminate purely optical vertigo. Taken in their crudity, these answers suggest the bare possibility that anaesthesia of the semicircular canals may confer some little immunity from this particularly distressing form of imaginative weakness.

CHINOLINE SALICYLATE IN OTORRHOEA.—BRIFFET ("Am. Jour. of Otol.," Oct., 1882) has been continuing his observations upon the salicylate of chinoline in otorrhœa, as to its effects in checking the purulent discharges and destroying the offensive odor. He has found better results from mixing the pure powder with powdered boracic acid in the proportion of one drachm of the chinoline salicylate to one ounce of boracic acid. The ear should be cleansed by cotton on a swab, and then the powder should be insufflated.

THE PROGRESSIVE GROWTH OF THE DERMOID COAT OF THE MEMBRANA TYMPANI.—BLAKE ("Am. Jour. of Otol.," Oct., 1882) has been making observations upon the direction of the movement of the outer superficial coat of the drum-membranes, which were conducted as follows: Small discs were cut from thin, double-sized foreign post or note paper, dipped in water, caught one at a time upon the end of a fine, cotton tipped, bent wire probe, carried into the ear under good illumination, and successively brought into contact with the membrana tympani, to which they immediately and firmly adhered, the warmth of the surface quickly setting the sizing. At intervals of from two to five days the ear was examined, and the movement of each disc recorded on a drawing. The discs, placed just posteriorly to the malleus, usually made a nearly straight line toward the posterior-superior periphery of the membrane, their lines of movement coinciding after they had passed the periphery and reached a point varying from two to five millimetres distant from the periphery, on the wall of the canal. The disc placed at the tip of the malleus described a slight curve and followed the line of its predecessors, but without overtaking them, being usually from one to three days longer in reaching the periphery. The third disc, placed in front of the tip of the malleus, described a still larger curve, and made its way also toward the posterior-superior periphery. The disc placed in front of the malleus, about half way between the tip of the malleus and the short process, made its way, more slowly than the others, in a nearly straight line toward the anterior-superior periphery, where it either continued directly outward along the superior wall of the canal, or else passed over the superior border of Shrapnell's membrane. From these observations it would seem that the most rapid clearing away of the dermoid coat of the membrana tympani occurs in that portion of the membrane the integrity of which is most important to its function of vibration with the malleus, and the most vigorous progressive outward movement of the lining of the canal occurs in the same line.

DILUTE MINERAL ACIDS IN THE TREATMENT OF CARIES, NECROSIS, AND EXOSTOSES OF THE EAR.—PRITCHARD ("Brit. Med. Jour.," Oct. 21, 1882) speaks highly of the efficacy of dilute mineral acids, preferably nitric acid, in cases of subacute and chronic inflammation of the bone with caries or necrosis of the walls of the external auditory canal, tympanum, or internal ear, and also of the mastoid process. The acid seems to dissolve the dead particles of bone and induce a healthy action. Should there be a piece of necrosed bone, more or less loose, but not free enough to be removed at once, the acid injections will be found valuable. The necrosed bone is in a position to be readily decalcified by the acid; and when the piece is thus softened, it can easily be removed by forceps, or, as frequently happens, it is unconsciously syringed out by the patient. The strength of the acid solution should be from one fourth to one half per cent. of the pure nitric acid, to which a little carbolic acid is to be added to render the solution more thoroughly antiseptic. The ear is to be syringed with this solution, warm, two or three times a day. In mastoid diseases, where a sinus back of the auricle exists, or an incision has been made, this wound or sinus should be syringed two or three times a day; and if there is any communication through the bone between the sinus and the tympanic cavity or canal, as often happens, the acid solution should, if possible, be syringed through from canal to wound, and from wound to canal.

In the case of exostoses, which either partially or completely block the external auditory canal, and which are complicated with suppurative disease, caries, or necrosis, the removal, or partial removal, of the bony obstruction is imperative; and here the acid solution may be of great value, either alone or as an adjuvant to the operation of drilling. He gives a number of cases in detail, showing the advantages of this method of treatment.

Letters to the Editor.

THE POLYCLINIC.

New York, December 23, 1882.

To the Editor of the *New York Medical Journal*:

SIR: In the editorial on the New York Polyclinic in the number of your journal for January 6th, it is stated that "the scope of the two schools varies in some matters of detail, undergraduates being admitted to the Polyclinic," etc. Will you allow me to correct this error? *None but legally qualified practitioners are allowed to study at the Polyclinic.* Of the sixty-four members of the class during the first six-weeks course, only three were admitted who were not graduates. These matriculated early in the session. The classes at the Polyclinic are now so well patronized by practitioners that henceforth none other than practitioners will be admitted. The Faculty feel gratified at the encouragement and support it has received from the medical press and the profession everywhere, and are making every effort to meet the demands of medical men for more thorough opportunities for practical study. This is evident from the fact that since our institution was opened, on the 23d of October, to date, December 23d, eleven hundred and sixty patients have been treated in the presence of the class.

JOHN A. WYETH, M. D.,

Secretary of the Faculty.

MISSTATEMENTS CONCERNING THE NEW YORK CODE.

To the Editor of the *New York Medical Journal*:

SIR: As the time for the meeting of the Medical Society of the State of New York approaches, it may be well to examine some of the misstatements that have appeared in various medical journals concerning the late action of the State Society in the matter of the new code of ethics. These may be summarized as follows: The new code was passed at an unusually small meeting, and rushed through without discussion by a horde of New York specialists. The facts are that the attendance at the meeting was larger than the average attendance at the meetings of the previous four years. An abstract of the discussion fills twenty-five pages of the published transactions. The New York specialists present were eleven in number, the total attendance being one hundred and sixty-nine. It has also been stated that the report of the committee was "sprung on the society without notice." The facts are that the report of the committee was printed in advance of the meeting, and a copy was furnished to each member in attendance prior to the session at which it was acted on, thus permitting all to thoroughly acquaint themselves with its nature.

The merits of the question were thoroughly entered into and decided, and we conceive that the only point really open for discussion is the question of expediency. It may be noted that in this State but two prominent objectors to the code have come to the front. One of them was within a week after its passage a violator of one of its important provisions—the one which sought to check newspaper advertising through the medium of reporters—and the other objector is not a practicing physician, but a manufacturing pharmacist. Two incidents have struck us as noteworthy: first, the meddling of the Philadelphia journals in a matter which concerned our State only, and not theirs; and, second, the meddling of the pharmacist in question in a matter that concerned medical practitioners only.

Yours, respectfully,

TRUTH.

A SUBSIDY TO PASTEUR.—The "Journal of the Franklin Institute" quotes "Les Mondes," to the effect that the French minister of agriculture has lately placed at the disposal of M. Pasteur a new sum of 50,000 fr. (\$10,000), in order to continue his admirable investigations upon the contagious diseases of animals. The government had already granted to the illustrious savant, for the same object, 50,000 fr. in 1880, and 40,000 in 1881. The minister consulted a special committee, who, in view of the brilliant success obtained by Pasteur in his previous investigations, unanimously recommended a renewal of the grant.

CELLULOID tracheotomy tubes are being tried in London.

New Inventions, etc.

A UTERINE SAW.

By CLEMENT CLEVELAND, M. D.,

ASSISTANT SURGEON TO THE WOMAN'S HOSPITAL.

THE accompanying wood-cut represents a saw designed chiefly for the operation of trachelorrhaphy, but it may prove useful in amputations and divisions of the cervix.

On both edges there is a double row of teeth, set backward, the object being to cut only or chiefly with the backward stroke, just as the jeweler uses the watch-spring saw. To be more explicit, the instrument is not to be used as a knife, but should be kept constantly against the tissue, and moved backward and forward with a gentle motion and light pressure. Used in this way, it makes a clean-cut surface.

The advantages claimed for the instrument are as follows: In cases where there is much cicatricial tissue, the operator has difficulty often in starting and even continuing the operation with the scissors, and finds recourse to the knife necessary, or at least an advantage. The objection to the knife, however, has been that too much hemorrhage is likely to follow its use. With the saw, the denuding is accomplished more rapidly than is possible with the scissors, and with less loss of blood.

It is not intended as a substitute for the scissors, but merely to supplement them, and can only be of decided advantage when the cervix is hard and cicatricial. In the ordinary case the scissors is by far the better instrument to use.

With this, as with the scissors, it requires a little practice to acquire the dexterity necessary to use it with ease.

Richardson's serrated scissors have been used in repair of the cervix, but they lacerate the tissues so much that union is imperfect. It was thought that this instrument would be open to the same objection, but thus far it has been used in three cases at the Woman's Hospital, with perfect union resulting in all.

Besides the shape figured in the cut, one has been constructed to fit Sims's knife-handle.

The instrument is manufactured by Mr. W. F. Ford, of the Instrument Department of Caswell, Hazard & Co.

Miscellany.

THE ROGUE BELLEVUE OF BOSTON.—Some of the corporators and officers of the Bellevue Medical College, of Boston, having been arrested on a charge of issuing bogus diplomas, and uncontroverted testimony having been offered by the prosecution that the concern had granted diplomas to persons grossly ignorant of medicine, and after a so-called course of instruction of a few weeks or less—the defendants simply maintained that the laws of the State allowed all this. The worst of it all is, that this defense could not be overthrown, and so the accused were discharged. This is an unusually flagrant case of imposition, in that the college bears a title calculated to lead the uninformed to look upon its degrees as having been conferred by one of the great medical schools of New York. In all other respects it can be matched in almost any of our large cities. How long will it take the public to learn that the protection of the medical profession means their own protection?

BODY-SNATCHING IN PHILADELPHIA.—In connection with the recent scandal in regard to the desecration of graves in Lebanon Cemetery, for the purpose of supplying anatomical material, the newspapers report that several arrests have been made, as the culmination of a clever piece of volunteer detective work done by the city editor of "The Press," assisted by a number of reporters. One of the accused is said to have made a confession, implicating some of the medical gentlemen connected with one of the colleges, two of whom have been placed under bail in \$5,000 each. It is to be hoped that the allegations on which the theory rests that these gentlemen were aware of the nefarious method resorted to by their purveyors of material may be shown to be false; and it is still more to be hoped that, if sufficient public provision is not now made for supplying the Philadelphia colleges with subjects, additional legislation to that end may be obtained promptly.

AN EXTRAORDINARY ANÆSTHETIC.—"Forest and Stream," an estimable paper for sportsmen, displays rare skill in concealing its sense of the ludicrous while treating its readers to a story of which the leading points are as follows: A German has invented and patented a device for alleviating the horrors of war—even doing away with them altogether. The invention consists of a gun throwing a hollow and fragile projectile filled with an anæsthetic of marvelous power. An entire army, it is said, can be put to sleep "instantly" by the discharge of one of these pieces, and the stupor is warranted to last for twelve hours, during which time the unconscious soldiers are made prisoners and carried off in ambulances, to await the declaration of peace. This improvement on the stink-pot is asserted to be perfectly harmless, notwithstanding its great power, and, besides its employment for military purposes, it is suggested that it may be used in hunting large game. The most ferocious brute falls helpless when hit by one of these missiles, so that the hunter is in no danger of coming to close quarters; while gentler animals are spared the pain of a lingering death from a shot that does not prove fatal at once.

THE DUBLIN ACADEMY OF MEDICINE.—Steps have been taken looking to a consolidation of the various medical societies of Dublin, under the title of an "Academy of Medicine," with the three grades of Fellows, Members, and Student Associates. There are to be four sections—Medicine, Surgery, Pathology, and Obstetrics; and two sub-sections—Anatomy and Physiology, and State Medicine. According to the "British Medical Journal," the Obstetrical Society seems inclined not to join in the movement.

THE EVETZKY TRAGEDY.—It is very much to be feared that our former contributor, Dr. Etienne Evetzky, is the person alluded to in a ghastly story that reaches us from the West. It seems that a Dr. Evetzky, having been publicly cowed by a woman, and suspecting his partner of complicity in the affair, shot the latter and then himself, both shots proving fatal. If our surmise as to the personality of the chief actor in this tragedy is correct, the poor gentleman must first

have become insane, for his rectitude and amiability were such that, with his mind unimpaired, even the most irascible of women could not have received at his hands such treatment as to lead her to attack him. Dr. Evetzky, a Russian by birth, was a resident of New York for several years, but somewhat less than a year ago he gave his friends to understand that he was about to take up his residence in a western city. He was a young man of noble presence, and his sad end will be deplored by a large circle of friends.

THE UNITED STATES DISPENSARY.—The Messrs. Lippincott, of Philadelphia, announce that the fifteenth edition of this standard work will be ready before the end of the month. The editors are Dr. H. C. Wood, Professor of Materia Medica and Therapeutics in the University of Pennsylvania; Joseph P. Remington, Professor of Pharmacy, and Samuel P. Sadtler, Professor of Chemistry, in the College of Pharmacy of Philadelphia. The revision is said to have been in all respects most thorough and complete, the new pharmacopœia being fully discussed, and the most recent non-official medicines, as well as those long out of date, being carefully considered.

RELIEF'S INJECTION FOR CHRONIC CYSTITIS.—According to "L'Union Médicale," this consists of crystallized phenic acid, dissolved, with the aid of a sufficient amount of alcohol, in from one thousand to two thousand parts of distilled water. Properly prepared, it is said to give rise to no pain, but to act as an astringent, modifying the denuded surfaces and hindering absorption. After having washed the bladder out with water of the temperature of the body, the solution is injected very slowly, until the bladder is well distended, so that the liquid comes in contact with every portion of its interior. The injection is then allowed to flow out, and the organ is again washed out with warm water.

DEATH OF M. HILLAIRET.—Professor J. B. Hillairet, the well-known dermatologist, recently died at the age of sixty-seven years. Some two years ago his service at the Hôpital Saint-Louis, Paris, closed by reason of his having attained the age of sixty-five, the age at which the hospital physicians of Paris are retired. Nevertheless, he was often at work at the hospital, up to the last, perfecting the data for his "*Traité des maladies de la peau*," only one fascicule of which has thus far appeared.

THE MEXICO-LEGAL SOCIETY.—The following named gentlemen were recently elected officers of the society: President, Mr. Clark Bell; First Vice-President, Professor R. Ogden Doremus; Second Vice-President, the Hon. Delano C. Calvin; Secretary, Mr. Leicester P. Holme; Assistant Secretary, Mr. Gilbert R. Hawes; Treasurer, Mr. Jacob Shraday; Librarian, Mr. R. S. Guernsey; Curator and Pathologist, Dr. Andrew H. Smith; Corresponding Secretary, Mr. Morris Ellinger; Chemist, Professor C. A. Doremus; Trustees, Dr. E. H. M. Sell and Mr. B. A. Willis; Members of the Permanent Commission, the Hon. A. G. Hull and Dr. M. H. Henry.

OBSTETRIC APPOINTMENTS IN PARIS.—The newly appointed hospital accoucheurs have been assigned to duty as follows: M. Budin to La Charité, M. Porak to the Saint-Louis, M. Ribemont to the Tenon, and M. Pinaud to the Lariboisière.

A FRENCH EDITION OF DIERING ON SKIN DISEASES.—To the high esteem in which Dr. Louis A. Dühring's treatise is deservedly held at home is now joined the additional field of the book consequent on its recent publication in French. The translation, with notes, is by MM. Toussaint Barthélemy and Adolphe Colson, and M. Alfred Fournier contributes a preface.

THE CHAIR OF ANATOMY AT HARVARD.—At a recent meeting of the Board of Overseers of Harvard University, Dr. Thomas Dwight, Instructor in Topographical Anatomy, was appointed to fill, for the remainder of the year, the chair of anatomy, made vacant by the resignation of Professor Holmes.

THE LYONS FACULTY OF MEDICINE AND PHARMACY.—M. Paul Cazeneuve has been appointed to the new chair of organic and toxicological chemistry.

THE MEXICAN "SNAKE MAN."—He is neither a mountebank nor an acrobat, says a *feuilletoniste*, in the "Gazette hebdomadaire de médecine et de chirurgie," but a poor fellow living in the village of Cuantla, in Mexico, affected with so singular a dermatosis that the physicians who have seen him are puzzled what to call it. The integument is greenish, and covered with scales closely resembling those of the rattlesnake—a resemblance still further heightened by a sort of autumnal moulting that the man undergoes every year. The skin does not fall gradually, in fragments, but is detached from large portions of the surface, so that the body looks like what is called in Mexico a "tuwon," a sort of bag of fresh skin with the bloody side out. A sister of this person died lately, affected with the same disease, having become blind by its extension to the eyes. The villagers speak of these persons only as rattlesnakes, and their disease is attributed to the fact that their mother, in order to cure herself of some affection of the blood, ate large quantities of the flesh of *Crotalus horridus*!

A NEW VEGETABLE STYPTIC.—"The Lancet" quotes from the "Neue freie Presse" a statement concerning a plant discovered during the French expedition to Mexico which, when chewed or crushed, exceeds in its styptic action all other substances yet known. Among the natives it is given a name that may be rendered *foamwort* (*Tradescantia erecta*, Jacq.). It has been acclimatized at Versailles.

CHOLERA is said to have been prevailing at Mecca since the 24th of October, and in Cochín China since the close of the summer.

ARMY INTELLIGENCE.—*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 13, 1882, to December 30, 1882.*—ALDEN, CHARLES H., Major and Surgeon. At expiration of present leave, to report to the commanding general, Department of Dakota, for assignment to duty. S. O. No. 273, par. 10, A. G. O., November 23, 1882. —McKEE, JAMES C., Major and Surgeon, now awaiting orders, is assigned to duty in the Department of California. S. O. No. 273, par. 10, A. G. O., November 23, 1882. —WILLIAMS, JOHN W., Major and Surgeon, assigned to duty at Fort Cœur d'Alène, Idaho. S. O. 161, par. 3, Department of the Columbia, October 26, 1882. —MOORE, JOHN, Surgeon. The leave of absence granted by S. O. 145, C. S., Department of the Columbia, extended one month. S. O. 175, par. 2, Military Division of the Pacific, November 3, 1882. —MOORE, JOHN, Major and Surgeon. The extension of leave of absence granted November 3, 1882, is further extended one month. S. O. 283, par. 4, A. G. O., December 6, 1882. —SMITH, ANDREW K., Major and Surgeon. At the expiration of his present sick leave, will be assigned to duty at Willet's Point, New York. S. O. No. 273, par. 10, A. G. O., November 23, 1882. —BARNETT, RICHARDS, Captain and Assistant Surgeon. The leave of absence granted November 1, 1882, is extended five months. S. O. No. 273, par. 11, A. G. O., November 23, 1882. —BROWN, PAUL R., Assistant Surgeon. The leave of absence granted May 25, 1882, is extended six months on surgeon's certificate of disability. S. O. No. 273, par. 7, A. G. O., November 23, 1882. —CALDWELL, DANIEL G., Captain and Assistant Surgeon. Leave of absence granted in Special Orders No. 105, October 3, 1882, Department of the Platte, extended three months. S. O. 279, A. G. O., December 1, 1882. —CLEARY, PETER J. A., Captain and Assistant Surgeon, now awaiting orders, will report to the commanding general, Department of Dakota, for assignment to duty. S. O. No. 273, par. 10, A. G. O., November 23, 1882. —CORSON, JOSEPH K., Assistant Surgeon, is assigned to duty at Jefferson Barracks, Missouri. S. O. No. 273, par. 8, A. G. O., November 23, 1882. —CRAMPTON, LOUIS W., Captain and Assistant Surgeon. Granted four months' leave of absence. S. O. 280, A. G. O., December 2, 1882. —GARDNER, EDWIN F., Captain and Assistant Surgeon. Ordered to Fort Walla Walla for duty. S. O. 161, par. 3, Department of the Columbia, October 26, 1882. —GORRAS, W. C., Assistant Surgeon. Relieved from duty at Fort Brown, Texas, and will accompany the Nineteenth Infantry to Forts Clark and Duncan, Texas. Their future stations will be announced. S. O. 130, Department of Texas, November 27, 1882. —MADDOX, T. F. C., Assistant Surgeon. Relieved from duty at Fort Brown, Texas, and will accompany the Nineteenth Infantry to Forts Clark and Duncan, Texas.

Their future stations will be announced. S. O. 130, Department of Texas, November 27, 1882. —POWELL, J. L., Assistant Surgeon. Relieved from temporary duty as attending surgeon at Headquarters, Department of Texas, and to proceed to Fort Davis, Texas, and report to the commanding officer for duty. S. O. 129, Department of Texas, November 23, 1882. —REED, WALTER, Captain and Assistant Surgeon. Relieved from duty in the Department of the East and assigned to duty in the Department of the Platte. S. O. 266, par. 4, A. G. O., November 14, 1882. —REED, WALTER, Captain and Assistant Surgeon. Assigned to duty as attending surgeon, Headquarters, Department of the Platte. S. O. 127, par. 2, Department of the Platte, December 4, 1882. —TAYLOR, MARCUS E., Captain and Assistant Surgeon. The leave of absence granted August 14, 1882, is extended two months. S. O. 283, par. 6, A. G. O., December 6, 1882. —GRAY, WILLIAM W., First Lieutenant and Assistant Surgeon. The leave of absence granted on surgeon's certificate of disability, October 31, 1882, Department of the South, is extended five months on surgeon's certificate of disability. S. O. 278, par. 3, A. G. O., November 29, 1882. —MUNDAY, BENJAMIN, First Lieutenant and Assistant Surgeon. Will be relieved from duty at Willet's Point, New York, and assigned to duty in the Department of the Columbia. S. O. No. 273, par. 10, A. G. O., November 23, 1882. —OWEN, WILLIAM O., Jr., First Lieutenant and Assistant Surgeon. To proceed to Astoria, Oregon, and report to First Lieutenant E. B. Rheem, Twenty-first Infantry, for duty with his command. S. O. 164, par. 5, Department of the Columbia, October 30, 1882. —WYETH, M. C., First Lieutenant and Assistant Surgeon. To report to Fort Snelling, Minnesota, for temporary duty. S. O. 185, par. 3, Department of Dakota, November 9, 1882. —PERIN, GLOVER, Lieutenant-Colonel and Surgeon. Granted leave of absence for one month, from the 19th instant. S. O. 217, Department of Dakota, December 20, 1882. —ALDEN, CHARLES H., Major and Surgeon. Now in St. Paul, Minnesota, to proceed to Fort Yates, Dakota Territory, and report to the commanding officer of that post for duty. Par. 3, S. O. 212, Department of Dakota, December 14, 1882. —BILL, JOSEPH H., Major and Surgeon. Will report to the commanding officer, Fort Omaha, Nebraska, for duty. Par. 4, S. O. 134, Department of the Platte, December 21, 1882. —BROWN, JUSTUS M., Major and Surgeon. Granted leave of absence for fifteen days. S. O. 119, Department of the South, December 11, 1882. —KIBOURNE, H. S., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply, through Headquarters Military Division of the Missouri, for an extension of two months. S. O. 218, Department of Dakota, December 21, 1882. —PORTER, J. Y., Captain and Assistant Surgeon. To proceed to St. Francis Barracks, St. Augustine, Florida, and to report to the commanding officer of that post for temporary duty. Par. 2, S. O. 119, Department of the South, December 11, 1882. —REED, WALTER, Captain and Assistant Surgeon. Relieved from duty as attending surgeon Headquarters Department of the Platte, and will report in person to the commanding officer, Fort Omaha, Nebraska, for duty. S. O. 134, Department of the Platte, December 21, 1882. —TERRILL, H. S., Captain and Assistant Surgeon. Upon being relieved from duty at Fort Omaha, Nebraska, will proceed to Fort Fred Steele, Wyoming, and report to the commanding officer of that post for duty thereat. Par. 5, S. O. 134, Department of the Platte, December 21, 1882. —BANISTER, J. M., Assistant Surgeon. To proceed to camp on White River, Colorado, and report to the commanding officer for duty. Par. 7, S. O. 250, Department of the Missouri, December 11, 1882. —HALL, W. R., Assistant Surgeon. Leave of absence for one month is granted. Par. 8, S. O. 250, Department of the Missouri, December 11, 1882. —HOPKINS, WILLIAM E., Assistant Surgeon. Granted leave of absence for two months, to commence January 1, 1883, with permission to apply for an extension of two months. Par. 1, S. O. 88, Military Division of the Atlantic, December 28, 1882. —MADDOX, T. F. C., Assistant Surgeon. To report to the commanding officer, Fort Clark, Texas, for duty. S. O. 138, Department of Texas, December 16, 1882. —WYETH, M. C., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence. Par. 4, S. O. 206, Department of Dakota, December 8, 1882.

Lectures and Addresses.

A LECTURE ON GASTRO-DUODENAL CATARRH IN YOUNG CHILDREN.

DELIVERED AT THE HARVARD MEDICAL SCHOOL, BOSTON.

By JOSEPH P. OLIVER, M.D.,
INSTRUCTOR IN DISEASES OF CHILDREN.

Physicians in general practice are often called to see and prescribe for little patients who present the following symptoms: They are delicate-looking, and one is told that for some time past they have complained of languor and weariness, particularly after slight exertion. They appear to be bright and fresh enough in the morning, but as the day wears on they are apt to be dull, and disinclined to play. When the hour to be dressed and go to the park arrives, they do not care to go out, but prefer to stay at home. Usually good-natured and amiable with their brothers and sisters or other companions, they now become peevish and fretful, complain of occasional headache, are restless at night, grind their teeth, have bad dreams, wake up suddenly in terror, and at times with pain in the legs. The appetite is capricious; to-day there is none whatever, to-morrow it may be voracious. After eating, they will frequently complain of pain in the region of the stomach and small intestine. The tongue is at times clean, and again it has a moist, milky coat, through which the papillæ show prominently. The tip and edges are usually clean, and not particularly red. The bowels may be constipated, or they may be so for a few days, and then a little loose, or the child may have a slight clay-colored operation daily for a week or ten days. The breath is at times very offensive. In the autumn or spring there is apt to be more or less follicular pharyngitis. Now, this condition of things persists till the child has what the mother calls a "bilious attack"—that is, headache, nausea, vomiting, and diarrhœa. The child is then in bed for a few days, and after that is a little better for a while, but in the course of a few weeks goes through with the same thing again. Occasionally there is a little cough; short and hacking during the day, but loose in the morning. The temperature is never above the normal unless the so-called "bilious attack" is protracted. Now, the foregoing symptoms go to make up what is called gastro-duodenal catarrh—an affection which, in my experience, is very common, especially in girls between the ages of four and twelve. Sometimes the symptoms are vague and indefinite. The patients do not have the explosive or so-called bilious attacks, and the parents do not seek advice until the condition of emaciation or a slight cough suggests the terrible name of phthisis. The symptoms often come under the head of that unscientific term, "general debility," and I am very sure that in children these symptoms mean nothing more nor less than gastro-duodenal catarrh.

The affection is often met with after some exhausting disease like pneumonia or typhoid fever; it may, however, occur without being preceded by either of those affections.

I presume that during the fever the system in general becomes so exhausted that the digestive organs partake of or share in the general weakness. In these cases the appetite is at times voracious, and, if the child is allowed to indulge it, the penalty for the indiscretion is generally pretty severe; an acute attack is developed with its train of distressing symptoms, such as pain in the head, nausea, vomiting, intestinal pain, and, perhaps, diarrhœa. As is well known, a child is not nourished by the bulk of food he takes into his stomach, but only by the food he can digest. In all children there is a constant tendency to acid fermentation of their food. This is very marked in feeble children; it may be due to their diet. The mucous membrane lining the intestinal tract is naturally active, and, on the slightest irritation, pours out suddenly and freely an alkaline secretion; if they have over-eaten, or if starchy food has too largely entered into the diet, fermentation is set up, and an acid is formed which stimulates the mucous membrane to further secretion. Now, this excess of mucus is the *fons et origo mali* under consideration, for it interferes with the digestion and absorption of food. As a result, the child is imperfectly nourished, and, from lack of nourishment, the symptoms of general debility, or, properly in these cases, gastro-duodenal catarrh, are developed.

As I before stated, the affection is more common in girls than in boys. With watchful parents some children seldom have the explosive attacks. The cases are less severe, but the child is half sick all the time.

During second dentition this affection is extremely common, and often mothers believe this process to be the occasion of the child's ill-health. Worms are also supposed to be the cause of the illness, and it is not surprising that mothers think so, for it is not unusual to find in these cases lumbrici or oxyuri. The excess of mucus which is secreted forms a favorable nidus for the development of the worm, and, consequently, the parasite is less a cause than a result of the disease.

The symptoms, then, may be briefly enumerated as follows. I refer to the subacute or chronic gastro-duodenal catarrh, not the acute affection. The so-called "bilious attacks" which occur in these cases are simply the affection rendered acute for a few hours or days, and need not be described in this lecture.

First, the child's appetite is capricious or fails altogether. He is constipated, and, perhaps, the constipation is followed by diarrhœa for a day or two. After this state of things has gone on for a time, he complains of feeling tired on slight exertion, is languid, indisposed to play. At times he is fretful and peevish, restless at night, grinds his teeth, wakes up suddenly with severe pain in his legs or in great terror. The child emaciates, the eyes are sunken and surrounded by dark rings. The skin becomes thin, harsh, and dry. There may be nausea and slight headache, with blurring of the eyes, and in older children, *muscæ volitantes*.

Through all this the tongue may be tolerably clean, or it may have a light milky coat, with the papillæ showing through prominently, the latter fact being generally significant of digestive disturbance in children. The so-called

"worm-tongue" may exist—that is, a tongue tolerably clean on the tip and edges, with a coating of shiny mucus in the center. The tongue is seldom markedly affected. The breath is often very offensive, though foul breath may be due to the disordered stomach or to buccal or pharyngeal catarrh. The cough which may be present is due to either slight bronchial catarrh, follicular pharyngitis, or elongated uvula. You frequently find hypertrophied tonsils in these cases, and the decomposition of the thick yellow secretion will account for the foul breath. Earache is not at all uncommon in these cases. I believe that I have before alluded to the occasional pain in the epigastric region after eating.

Now, having made a careful examination of the little patient, and having come to the conclusion that the symptoms are due to gastro-duodenal catarrh, having recognized the weakness of the digestive system, and having seen the evidence of defective nutrition, our indications for treatment are plain enough. We must increase the nutrition—that is, increase the supply of food, but at the same time we must be careful in our selection, as the fact that the digestive system is feeble must ever be before us.

Treatment.—First, the diet is to be arranged; as the tendency to fermentation is so marked in these cases, I eliminate the starchy foods as much as possible. You can not deny a child of from six to twelve years bread and potatoes altogether, but you can arrange an agreeable and varied diet, so that he shall get a minimum quantity of these articles. Many physicians believe that such cases would be benefited if oatmeal and cracked wheat should enter more largely into the diet; it is not so, however, according to my experience. It seems to me that oatmeal and cracked wheat illustrate most admirably the old adage that "what is one man's meat is another man's poison." Particularly in the summer season should the oatmeal be interdicted. In these cases I generally order a cup of weak mutton-, chicken-, or veal-broth to be given to the child as soon as he wakes in the morning, before he gets out of bed even; a good-sized tea-cupful is enough; of course, it must be warm. Then an hour or so later a little toasted bread or stale French bread. The crust of the long French roll is excellent, and children usually like it. With the toast or French bread may be given a cup of milk and a hard boiled egg chopped fine, to which may be added a little butter and salt, or, better still, a little cream, or, in place of the egg, a little broiled fish. Some children will object to the milk, and in such cases you will do well to prescribe Schweitzer's cocoatina, Cadbury's cocoa essence, or Fry's cocoa powder. Children, as a rule, like the cocoa or chocolate flavor, and do not object to the milk when so disguised.

At noon a dinner consisting of beefsteak, chop, a little bird, roast beef or mutton, not too much cooked, with meat gravy; but no made gravy or sauce is to be allowed. At night dry bread and milk. The broth, if not too rich, may be repeated at this meal. Some mothers think this a pretty limited diet, but you should vary it as much as possible, and give four or five small meals a day instead of three larger ones. As the excessive production of mucus in the stomach and intestine is to be overcome gradually

and by constant efforts, I endeavor to attain this result in two ways: first, by diminishing the production—that is, by regulating the diet; and, secondly, by clearing out the excess or over-production by means of cathartics regularly administered every third or fourth day. As cathartics I use the aqueous tincture of rhubarb, licorice powder (German), pil. rhei. comp., and occasionally the following powder: \mathcal{R} Calomel, 1 part; pulv. jalap., 2 parts; pulv. scammony, 2 parts. *M.* To be given in syrup.

In mild cases the following recipe has often done good service, obviating the necessity of the regular administration of a cathartic: \mathcal{R} Podophyllin, gr. j; alcohol, 3 j. *M.* Five to ten drops on a lump of sugar morning and evening. The indications for this are constipation, clay-colored stools, and loss of appetite. I do not expect to get a cathartic action from the remedy, for if it produces such an effect it must be used in smaller doses or abandoned altogether. It is to be given for two or three weeks, or even longer. Under its use I have seen the tongue clean, the appetite return, and follicular pharyngitis disappear completely. Under the above circumstances some physicians will order four or six grains of calomel; but as it is very unpopular treatment among many of the laity, I seldom employ it, particularly as other things seem to act as well. One word more in regard to the podophylline: If the patient should have two or three dejections a day, the dose must be diminished about one half. The good effect of the medicine is not seen for several days. After cathartics, alkalies are of next importance—the bicarbonate of soda or potassa, given in a bitter infusion, say cascarrilla, chiretta, gentian, or columbo. If the mucous membrane generally is in a lax condition, to the foregoing bitter and alkali you may add a little tincture of myrrh. As it gives a disagreeable taste to the mixture (already disagreeable enough to the young patient), I would omit it from the prescription unless you consider that the patient really requires it.

The bitter is usually intensely disagreeable to children, and sometimes it is a difficult matter to get them to take it regularly; but if the mother understands the importance of the drug she will make the child take it. Tincture of nuxvomica or liquor strychniae are sometimes useful adjuncts to the bitter infusion. They, of course, render it still more bitter. The objection to syrup is obvious. La Bourboule water you will often find useful. This is a natural arsenical water which comes from La Bourboule, Auvergne, France. The arseniates play the most important part in this water, owing to the powerful action which they possess in a small volume and in a proportional large dose, as they are found in the Bourboule water; no other mineral water known contains so large a proportion. Nowadays it is a favorite remedy with dermatologists; it is indicated in cases of gastro-duodenal catarrh where you find as a complication obstinate post-nasal and pharyngeal catarrh, and in patients who have the so-called herpetic diathesis, which shows itself by the familiar cutaneous lesions of certain forms of psoriasis, eczema, etc. It should be given warm, after meals, in quantities of one to three or four ounces three times a day, and should not be continued beyond three weeks. Its administration may be resumed after a fortnight.

As the child improves, a little iron may be added to the treatment, but of the milder forms and in very small doses. A little later many children bear cod-liver oil well. Wines, such as dry sherry or good claret, may be given with dinner. Baths are a useful adjunct to the treatment—I mean sponge-baths.

PREMATURE DELIVERY FOR THE PREVENTION OF BLINDNESS.*

By EDWARD G. LORING, M. D.,

NEW YORK.

So far as I know, and so far as I have been able to inform myself by inquiries among my professional brethren, premature delivery for the sole purpose of preventing blindness has never, up to the present time, been performed, or even advocated.

In suggesting any new remedy, or remedial procedure, especially in so conservative an art as medicine, two things ought to be considered: first, whether there is any necessity for the remedy proposed, and, secondly, whether the advantages attending its adoption will outweigh the evil effects which existed before the remedy was suggested.

First, as to the necessity of the operation.

It has been long known that pregnant women, especially toward the end of gestation, were liable to suffer from a disturbance of vision, which might vary from the slightest deterioration to a total and permanent blindness.

Physicians were well aware of this fact before the true condition of retinitis albuminurica, or uræmic amaurosis, was known—that is to say, prior to the time of Bright, and long before the invention of the ophthalmoscope.

The fact, therefore, admitted, that possible, and, under some conditions, inevitable blindness may ensue, the question reduces itself to the simple inquiry whether premature delivery is ever justifiable either for the restoration or for the preservation of sight.

It appears to the writer that there are not a few cases in which it is not only justifiable, but where the true principles of sound practice demand its adoption.

The reasons for this belief will perhaps be better explained by the following cases, which are cited simply as useful examples of what may happen, and not unfrequently does happen, either directly or indirectly, in the experience of every physician and oculist.

The following case is reported by Mr. Robert Lee,† the particulars being furnished to him by Mr. Bowman.

On the 7th of December Mr. Bowman was consulted by a lady who was pregnant, and "who had rather suddenly lost her sight in great measure." The urine was found to be excessively loaded with albumin. At Mr. Bowman's suggestion the patient consulted Mr. Paget and Dr. West, who anticipated, Mr. Bowman says, as he did himself,

"that the confinement would be attended with convulsions of a dangerous character." On the 9th of January, or one month later, the patient had a premature confinement of a male fetus which was still-born. The patient gradually regained her health and strength, but Mr. Bowman regrets to state that the sight has only partially returned.

The first thing which strikes one here is that there was a permanent loss of vision, and the question arises whether something might not have been done to prevent it. It is stated that on the 7th of December the patient had rather suddenly lost her sight, and, if there ever was a chance of saving it, it was by getting rid of the cause as soon as possible, as it is universally acknowledged by all oculists that the sooner the delivery takes place the better the prognosis for sight. Nothing, however, was done, notwithstanding the fact that the three attending physicians, all men of great eminence, had announced that they anticipated that when the confinement did take place it would be attended with dangerous convulsions.

No action, however, was taken, and the woman would have been allowed to remain blind to the end of her term unless nature had stepped in with a premature birth. At any rate, she was allowed to remain blind for an entire month with the urine loaded with albumin; and what a month's delay under these circumstances will and often does produce in so delicate a tissue as that of the retina and optic nerve is too well known to need any comment. Would it not have been better practice, nay, was it not the bounden duty of the surgeons in a case in which a great degree of blindness was actually present, and danger to life anticipated, to have produced premature delivery and not waited for an entire month for the chance intervention of nature, and to have in the end to regret that "the sight had only partially been restored"? Does not the mere fact that the sight did partially return after the patient had lost it for a month show that if the delivery had taken place earlier there would have been every chance of its being fully restored? and is the sight of a woman in the prime of life of so little account that no effort should be made or no risk run to prevent it, especially when it is anticipated that later on there will be danger to her life itself?

The literature for the last half century, as everybody is aware, is full of such cases, and that related above is cited simply for purposes of illustration.

The following case by Mr. Lawson* is a sad example of the misery which may be entailed upon a patient by recurrent attacks of blindness occurring in successive pregnancies:

B. S., aged forty-one, applied to the hospital on December 2d of this year, suffering from the following amaurotic symptoms: She was the mother of nine children, six of whom were now living. She said that in the second month of her pregnancy with her eighth child her sight began to fail her, and continued to get worse until the termination of her pregnancy. She could then only see large objects; she could not count fingers, nor tell a man from a woman. She could merely see that something large was in front of her.

* Presented to the American Ophthalmological Society, July, 1882.

† "Medico-Chirurg. Trans.," vol. xlvii, p. 171.

* "Ophthal. Hosp. Reports," vol. ix, p. 65.

After the birth of her child her sight began to improve, but not until after she had begun regularly to suckle it; and in three months' time she was able to read her Bible, the print of which was about the size of No. 10 Jaeger, and she could not only see to do needle-work, but actually did it. In this state she continued for two years, when she again became pregnant with her *ninth* child, and her sight at about the second month again began to fail her and continued to diminish until at the ninth month she could see no more than she did at the time of her previous confinement. After the birth of this child her sight only slightly improved compared with the improvement which followed the birth of the previous one. This she attributes to the fact of her being unable to suckle her child on account of her bad health. She regained, however, sufficient vision to be able to walk about unguided and to carry her child with her in the streets, and, although she could easily distinguish the faces of her friends, still she had not sufficient sight to be able to read or write. Eighteen months have elapsed, and she is now pregnant with her *tenth* child. The increased impairment of vision came on about the second month as on the two previous occasions, but her sight has failed her this time much more rapidly, and on that account she applied to the hospital.

She is now six months advanced in pregnancy, and the following is the condition of her sight:

Right Eye.—No perception of light; pupil fixed, and widely dilated.

Left Eye.—Is unable to count fingers, but at eight inches can just make out the hand; pupil dilated, but with a very slight range of action.

Examined with the Ophthalmoscope.—The optic entrance looks small, of a bluish pearly white; the arteries appear like mere threads, while the veins are very large.

She suffers now, and has suffered during her pregnancies, with pain at the top and back of her head. The least noise "seems to bewilder her," and she arises in the morning with headache. She has no loss of power in any of her limbs, but looks thin and haggard, having the appearance of one who has gone through much trouble.

A striking feature in this case, and one which is thought to be uncommon, though it is by no means so rare as is supposed, is that the vision began to fail so early in the pregnancy—that is, about the second month—and that it occurred in three successive pregnancies at this time. Now, notwithstanding this fact, and that with each pregnancy there was an additional and serious increase in the loss of the sight, the patient was allowed to go through three successive pregnancies until she became totally blind without an effort being made to prevent it. No wonder she looked, as the reporter of the case expresses it, "thin and haggard, having the appearance of one who has gone through much trouble." To be blind at forty-one with eight or ten children to look after is not a cheerful prospect for any woman. To be allowed to become so through a succession of years would seem, if possible, only to add to the misery. Other cases precisely similar might be cited here, as they are familiar to every accoucheur.

Such being the condition of affairs when matters are

left to themselves, it remains to be seen what occurs when interference, either natural or artificial, takes place, and in illustrating this I would briefly cite another case from Mr. Lee:

On the 29th of January, 1863, Mr. Lee saw a young lady in the third month of her pregnancy. She was suffering at that time from sensitiveness in the region of the uterus, sickness of stomach, and general nervous irritability; the pulse, however, was not very rapid, and there were no symptoms to excite alarm. On March 21st, or two months later, he received a note from Mr. Bowman desiring a consultation, as the patient had consulted him for defective vision. "The urine was loaded with albumin, and there was a destructive disease going on in the coats of the eye." As the patient was in the sixth month of her pregnancy, and as she seemed to be threatened with convulsions, and especially as these symptoms became urgent in the following three days, premature delivery was proposed by Mr. Lee, as he believed the affection of the kidneys and eyes arose from the pregnancy. Before, however, having recourse to this, it was considered proper to hold a consultation with Dr. Robert Ferguson, who thought it unadvisable to induce premature labor, "chiefly on the ground that the life of the child would necessarily be sacrificed, as the pregnancy had not advanced beyond the sixth month." It was determined, in consequence of this opinion, not to interfere, but to wait and see what course the disease would take. On April 10th, or three weeks later, there was an attack of convulsions; and, as these were sufficient to excite apprehensions that fatal puerperal convulsions would take place, it was considered proper, after a second consultation, that premature labor should be induced immediately. This was successfully performed, and, with occasional drawbacks, the patient continued to recover for the next ten days, when she could distinctly see the figures on the dial of a watch.

The happy result in this case and the restoration of vision were, it can not be denied, due to the induction of premature delivery, which removed the cause producing the loss of sight; and the only criticism to be made is that it was not induced as speedily as it should have been, since the operation was delayed until dangerous convulsions had already taken place, notwithstanding the fact that precisely this result had been anticipated, and in spite, also, of the fact that "a destructive disease was going on in the coats of the eye, and that the urine was at the same time loaded with albumin." Neither would it seem that the reason given for the delay—that the life of the child would be sacrificed—was a good and sufficient one, since, from the very nature of the trouble and the condition of the mother, there was every reason to suppose that, sooner or later, not only the life of the child was sure to be sacrificed, as it ultimately was, but also that of the mother would be imperiled. Here, too, the question narrows itself to whether the *possible* life of a sickly child ought to outweigh the probable loss of sight in the mother, and whether it is good practice, or even justifiable, to run such a risk.

A still more instructive case is reported by Brecht, of Berlin.*

* Graefe's "Archiv für Ophth.," B. xviii, Abth. ii, p. 111.

A woman, thirty-six years old, noticed in the third month of her sixth pregnancy a disturbance of her vision. In the fifth month, that is, two months later, she was seen by Dr. Brecht, who detected well-marked organic changes in the retina and optic nerve. The urine was highly albuminous. In October, or three months after the first notice of a loss of vision, eclamptic attacks took place, which lasted twenty-four hours, with a further reduction of vision to such a degree that the patient could not recognize persons in the room. After waiting some days, artificial premature labor was induced by the introduction of a catheter, which was accompanied by further convulsions. On the tenth day after the operation there was a manifest reduction in the quantity of albumin, and vision had improved to a considerable degree. Five weeks after the operation the vision in both eyes had returned to the normal amount ($V = 1$). A year later some of the ophthalmoscopic appearances still remained, while others had entirely disappeared, but the vision in both eyes was still perfect.

The result here, like that in the former case, is all that could be wished for; but the same question arises whether it would not have been better, from a clinical point of view, to perform the operation at the third month, when the loss of vision was first noticed, instead of waiting until the fifth, when convulsions had already set in, and which surely vitiated the prognosis, not only as regarded the preservation of sight, but also the life of the mother.

Brecht also reports a marvelous case of separation of both retinas during gestation, and where readjustment of both retinas took place after a premature birth, which occurred without any artificial intervention. Others have reported similar cases, and the restoration of vision after parturition in cases of kidney disease dependent upon gestation is so common as to need no comment.

In all the foregoing cases it will be noticed that no interference ever took place until the patient was actually suffering from some grave constitutional disturbance. The following case differs from those hitherto reported in the fact that no such disturbance was present at the time of the operation:

E. B., aged thirty-five, consulted me for failing sight. The patient was a married woman whose general health had always been good, the only departures from which condition were during her pregnancies. She had been married eight years, and had had three confinements in that time. Until within a short time of the birth of her first child she had had no loss of sight. She was, however, highly hypermetropic, and had been compelled on that account to wear glasses, especially for reading and sewing. She had never suffered any pain in her eyes, nor did she at the present time. She consulted me simply on account of failing vision. All other organs and functions seemed to be normal, and a careful examination as to heart, lungs, and kidneys gave no evidence of disease.

Her attention was first attracted to her eyes about two weeks before her confinement with her first child. She first noticed that she could not see people or objects when they were on the left side of the left eye. She stated that the trouble came on rather suddenly about two weeks before

her delivery, when she noticed a dimness of vision in this part of the field. This seemed to her like a bright cloud or mist, which was replaced in part at a later period by a broad dark band, which ran like a stripe across a bright ground. After her confinement the bright ground disappeared, not, however, until her menses reappeared. The dark band, however, remained, and no object could be seen when carried beyond a certain distance toward the left.

Just before her second confinement precisely the same thing occurred, and the dark band increased in breadth so much that she could not see objects with the left eye when she looked straight at them—in other words, central vision with this eye had begun to be affected; indeed, was so far gone that it was only by turning her head so as to bring the objects into the temporal side of the retina that they could be discerned at all. The "sight of that eye was nearly all gone," but up to this time that of the right eye had remained unimpaired.

A short time before her third confinement precisely the same thing occurred in her right eye as had taken place with the left, and it was in regard to this that she came to consult me first, in October, 1879. This was three months after her confinement, and her vision began to fail two weeks prior to it. The patient was in much mental distress in regard to the loss of sight and the fear of approaching total blindness, and her bodily health was beginning to be undermined.

The examination of the eyes gave the following result: Vision was entirely gone in the left eye, with the exception of a quantitative perception of light in a narrow district of the inner field. Vision in the right eye was also so reduced that the patient could not, as she expressed it, tell the faces of her own children. She could barely count fingers at a few feet. In this eye, too, the field of vision was reduced at the outer side. That is to say, the nasal portion of each retina did not perform its function.

There was no improvement of vision with glasses. The ophthalmoscope showed that the media were perfectly clear. The optic nerve gave the picture of white atrophy of that peculiar kind in which the capillary circulation seems to have suffered the most. In neither eye were there any capillaries whatever to be seen upon the disc, while the larger vessels seemed to have preserved their normal condition as to size and course. The light streak upon the vessels was well marked, and there was no sign of any form of retinitis to be detected. Had it not been for the unmistakable and conspicuous whiteness of the disc, the fundus would have been pronounced normal.

As the case was a loss of vision incident to labor, careful and repeated examinations were made as to the condition of the kidneys as well as the heart and lungs. No trace of albumin was ever found, nor was there any other departure from a normal standard in any of the other organs.

The treatment consisted at first in the use of injections of strychnine, which were carried to the very verge of toxicological effects. Then the changes were rung on the mercurials, iodides, and tonics without the slightest avail, and at the end of a month vision was no better than at the beginning of the treatment. At the end of this time the menses

returned, and from that moment a gradual but decided improvement in sight took place, so that at the end of another month the patient could see with her right eye "to do almost anything." Tested accurately, the vision amounted to one third of the normal quantity ($V=\frac{1}{3}$). There was, too, a reduction in the field of vision, and objects situated at the right of the median line were not so clear as on the nasal side of the field. The patient was, after a little longer interval of surveillance in order to watch the case, dismissed, with a caution to guard against any imprudent use of the eyes, and a most emphatic caution and warning, at the risk of her sight if not her life, not to become pregnant again.

For the next eighteen months I saw no more of her, when she came to me in great alarm, because she was again "in the family way," and she feared, from what I had said and from her past experience, that if the child was carried to the full term she would become blind, and lose the entire sight of the right eye precisely as she had already lost that of the left. She informed me that she had already communicated the facts of her history, together with the warning I had given her, to her family physician, and, at his instigation, she had called upon me to obtain my opinion as to the necessity of a premature delivery. I then made an examination of the eyes, and found that since I had seen the patient not only had the vision not decreased, but had even improved, it being, at the time of the examination, April, 1881, two fifths of the normal against two sixths of the year before. I could only repeat the warning that I had already given—that is, that at each pregnancy there had, and always would be, not only danger to her sight, which, in my opinion, would inevitably be lost, but also that there was danger to her life. I reiterated this opinion when the family physician called upon me, and that I could see no escape if she was allowed to have another child, if not from death itself, at least from a doom that, in my opinion, was worse than death—that is, total blindness at an early age with three or four young children dependent upon her. I was led to this conclusion from the fact that it was absolutely undeniable that the loss of vision was dependent upon the advanced condition of gestation, that the attacks did not come on until just before the time of delivery, and that each attack had been followed by a loss of vision which had totally destroyed one eye and had threatened destruction of the other, from which there had been a marvelous, but at the same time only partial, recovery, and lastly, because during the past sixteen months, when the menses had been regular and the health restored, the remaining eye had not only not deteriorated, but had even improved in vision.

Premature delivery was produced on May 1st, when the fetus was three months old. There was considerable reaction after the operation, the patient remaining in delicate health all the summer. She returned to see me again in November, 1881, when she reported that, notwithstanding all the sickness incident to her miscarriage, her vision had certainly become no worse, and she thought a little better; and this was shown to be the case, for the vision had risen to a little better than one half of the normal amount against two fifths at the former examination. The ophthalmoscopic

examination showed, however, the same appearances as to paleness of the optic nerve and want of capillary circulation. There was not a capillary to be seen upon the disc.

This is, so far as I know, the first case in which an abortion has been performed where the most prominent if not the sole symptom was a loss of vision. It is, however, not the first case in which, in my opinion, it should have been done; and I think, if the importance of the matter were better appreciated, the necessity for it might appear more frequent than is supposed.* I have from time to time been consulted by women who have been confined within a shorter or longer period, and who have told me that they began to complain that their sight was becoming affected before their confinement, and that they had been assured by the attending physician that "it would come all right as soon as the child was born."

That it does come all right in some cases, or what appears to be all right, is often true, but there are many cases in which it not only does not come all right, but in which a deterioration of sight is sustained which may vary from a slight impairment to an absolute loss of all useful vision. It happens as a common occurrence to the oculist to hear the first complaint in failing sight referred by the mother to about the time she had her first child. White atrophy of the optic nerve is certainly a rarer disease in women than in men, but, according to my own experience, it occurs much more frequently in women who are married than in those who are not, and at a much earlier age. I do not mean to say that in every case where atrophy is detected in a pregnant woman an abortion should be performed, but I do say that, where it has occurred in one confinement, every precaution should be taken to explain the dangers of future confinements to the patient, and that in extreme cases, such as the one reported above, premature delivery should be performed rather than let the mother go blind, or run the fearful risk of going blind.

If this is true in regard to the comparatively rare disease of atrophy, it is doubly true in albuminuria, so much more frequently found in pregnant women, and with which we so frequently find the so-called retinitis albuminurica.

Very little attention, even at the present day, I find, is paid by the general practitioner to the condition of the urine in pregnant women unless his attention is particularly called to it by some developments in the symptoms or some derangement in function.

In the larger medical centers it is true that some very careful physicians do make an examination of the condition of the kidneys from time to time, even if there are no manifestations which make it a necessity; and I have been informed by such careful attendants that, if any albumin is de-

* Since this case was reported at the Ophthalmological Society, my colleague at the Infirmary, Dr. Moore, has advised the induction of premature delivery for the preservation of sight in a woman who was eight months pregnant, and in whom vision was very much reduced and threatened to become extinct. At the time of the operation, the vision in the right eye was only equal to $\frac{1}{16}$ of the normal, and in the left eye there was only perception of light. There was retinitis in each eye, and the urine was loaded with albumin. After the expulsion of the fetus vision rapidly improved until it reached $\frac{1}{2}$ in the right eye and $\frac{1}{4}$ in the left—at which degree it remained permanent.

ected, a strict watch is kept upon the condition of the eyes, and, in case any complaint is made of the vision, a careful examination is obtained, oftentimes at the hands of an expert; and with one invariable result, no matter how serious the inflammation of the retina may be, and that is that the only course to pursue is to wait until the child is delivered, with the knowledge that the retinitis will subside as soon as the birth takes place, and with the hope that the delicate nervous elements involved will survive the secondary contraction and atrophy which will follow.

But it often happens that no complaint—not even the slightest—is made by the patient as to her eyes during the entire pregnancy, or at the time of her delivery, and yet a low stage of retinitis, or indeed one of great intensity, may exist. Indeed, the vision may remain perfect, or nearly so, for a long time, and only begin to fail long after the active signs of inflammation have passed away, and the secondary or atrophic stage sets in.

Thus, I have seen women who only began to complain of a loss of sight some four or five months after their confinement, since the subsidence of the first, or inflammatory stage, had been so slow, and the advance of the secondary, or atrophic stage, so insidious that the patients themselves have not noticed the gradual loss of vision until this has been considerably affected, which then admonishes them to seek the advice of an oculist. I have certainly seen if not many, still a goodly number of cases in which the patient herself did not attribute her loss of vision to her confinement, but to some ulterior cause, but where, from the ophthalmoscopic appearances, the undoubted evidences of a retinitis albuminurica still existed, and where a close questioning of the patient or her attending physician corroborated the fact that albuminuria had existed for a longer or shorter period before the confinement.

It may be, and no doubt will be, urged that the reason why no interference has taken place hitherto until the patient was actually suffering from some grave constitutional trouble which threatened life was, that such interference would be unjustifiable, both on moral and on legal grounds.

As for the moral aspect of the case, or what in some minds passes for such, I have neither the time nor the inclination to go into so wide a field of discussion. There may be physicians who, as physicians, even unrestrained by legal considerations, might think it right that the highest and most useful of all our senses should be sacrificed rather than that any interference with the workings of nature should take place. From a mere medical standpoint it is hard to conceive of such a thing, and that is all that interests us here.

From a legal point of view, it is also hard to conceive that there can be but one opinion, and that is in favor of the operation when the circumstances are such as demand it. The law states that premature delivery shall not be performed except for the preservation of the life of the mother or the child, and it is precisely for the "preservation of life" that it would be done when the eyesight is threatened, for the one is part and parcel of the other, and in operating to save the sight we are operating to save life. Thus, Simpson many years ago declared, and the opinion is universally

upheld at the present day, that symptoms such as headache, giddiness, derangement of sight, are merely premonitory symptoms of puerperal convulsions, and when these are associated with albumin we may be certain of the liability of our patient to the supervention of convulsions. Moreover, it so happens that these derangements of vision occur at a time when, as Graefe puts it, "the prognosis for life is even worse than for sight." Given, therefore, a pregnant woman, with loss of vision, or organic lesion of the retina or optic nerve, as the prominent, or even as the sole symptom, no one can say that a series of convulsions may not set in at any moment which will carry everything before them, including not only the life of the child, but also that of the mother.

There is another point of great importance, and that is, that where an attack of uremic or albuminuric amaurosis occurs in one pregnancy it is almost certain to repeat itself in the following ones; and if the life of the mother has been threatened in the one case, and from which fate there has been a lucky escape, it may also be threatened in the following pregnancies, from which there may be no escape.

From the cases which have been reported above, and from the arguments based upon them, I would conclude:

1. That examinations as to the condition of the eyes of pregnant women should be made much more frequently than they now are; and that these should be made in a routine manner, even when the patient does not complain of any disturbance in vision, since it has been discovered that about one third, or thirty-three per cent., of those who have an organic lesion of the retina or optic nerve from kidney trouble either have none or make no complaint of any reduction of vision. This seems almost incredible to the general practitioner, but the ophthalmologist has become only too painfully aware how often, and for how long a time, eyes may be affected with an inflammatory process of great intensity and yet give rise to no complaint on the part of the patient. Thus, a retinitis or a neuro-retinitis, which, in its primary stage, may exist, and often does, for months unsuspected by either the patient or physician, may lead, after a long interval, through the secondary or atrophic state to complete blindness.

From the fact that no complaint is made of any loss of sight until near the end of the pregnancy, it has been assumed that the trouble did not begin until that time. I am inclined to think, however, that, while this is no doubt true, especially of the cases of uremic origin, there are very many cases, especially those dependent on albuminuria, in which the trouble really began long before; and that the eyes, if examined, would often have given evidences of disease long, oftentimes months, before the explosion took place which has cost many a mother her eyesight, and oftentimes her life, both of which, by a timely examination and a timely operation, might have been saved. I will even go so far as to say that I believe that the symptoms of albuminuria not infrequently show themselves in the eye before any manifestation can be had in the urine.

It will be said at once that it is requiring too much of the general practitioner to suppose that he shall attempt the recognition and use so difficult and intricate

cate an instrument as the ophthalmoscope. That the ophthalmoscope in its widest sense is one of the most difficult of the instruments used for the detection of disease is, I admit, perfectly true, as it is that few obtain a perfect mastery over it. But the same is true of the microscope. To one great microscopist there are thousands who daily use the instrument with the greatest success in the detection of disease, and it might, with a little attention, be the same with the ophthalmoscope. Much as I admire the high standard of skill which some of those specially trained to its use naturally acquire, nevertheless, I firmly believe that the sphere of its greatest usefulness, and therefore of its greatest triumphs, will one day be in the hands of the general physician, and especially in those of the obstetrician. Thus, Mr. Eales reports that a single physician was able to furnish him for examination, from a single hospital in Birmingham, twenty-eight cases of neuro-retinal disease from kidney trouble in one year, while out of 11,000 cases of general eye disease at the eye infirmary only four such cases were seen.

2. I would conclude that where a marked deterioration of vision has occurred, with or without ophthalmoscopic changes, and where blindness is threatened, premature delivery is not only justifiable, but often demanded.

3. When a permanent loss of vision has occurred from a preceding pregnancy, premature delivery in a subsequent one, when surrounded by its proper safeguards, is not only justifiable, but at times absolutely necessary; and that, further, when a loss of vision, either temporary or permanent, has once resulted from gestation, it is the duty of the family physician or obstetrician to explain, both to the wife and husband, that the cause of the trouble is a constitutional and not a local one, and that there is every probability of recurrence of the trouble in succeeding pregnancies which may lead, not only to the destruction of vision, but even to loss of life.

CASES OF INTESTINAL CANCER.*

By FORDYCE BARKER, M. D., LL. D.,

PROFESSOR OF CLINICAL MIDWIFERY AND DISEASES OF WOMEN IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE following cases are narrated as possessing certain clinical features of interest:

In the *first case* the patient, a man, began to have pain in the right iliac fossa, at the caput coli, in February last. There was considerable swelling at the seat of the pain. Some nausea and vomiting occurred, and great prostration came on suddenly. As I was out of town at the time, the late Dr. James R. Wood was consulted, and came to the conclusion that there was some inflammatory induration and accumulation of feces at the caput coli. I saw the patient three or four days after the first attack. The tumor was then of considerable size. The patient was in bed, and the treatment was being carried out as recommended by Dr. Wood, namely, large injections of soap-suds, and ox-

gall and aloes as laxatives. It was said that the tumor had diminished very considerably, and the vomiting had ceased, but there was still a good deal of tenderness in the iliac fossa. I directed that the treatment should be continued, and recommended a poultice in addition, as there seemed to be considerable inflammatory action. The patient felt great relief from the use of the poultice. There was a good deal of jaundice, together with loss of appetite and a disposition to constipation, for which latter condition I ordered large doses of phosphate of sodium for three successive days. Large evacuations of fecal matter were thus procured, and a tumor only as large as one's thumb remained at the caput coli three days before I left the city for the summer, which was on the 2d of June. The patient, however, was cachectic and very easily fatigued, and I suspected some malignant disease of the intestine. He spent the summer out of the city, in comparative comfort, until the 3d of August, when he began to suffer from pain at the seat of the tumor, and to emaciate rapidly. The pain became extreme, and large doses of morphine were required to give relief. A few days before returning to the city, which was the 3d of October, a fistulous opening formed from the caput coli into the bladder, allowing of the passage of fecal matter and flatus through the urethra. When the patient arrived in the city I found that the tumor was as large as one's fist, irregular, and nodulated. He was suffering from nausea, which was probably due to the opiate; his appearance was extremely cachectic, and there was an odor about him suggestive of some putrid infection. There was no hæmorrhage from the bladder, nor was there any difficulty with urination. The bowels were pretty regular. Death took place on the 20th of October, sooner than I had observed in any previous case.

In the *second case* the disease dated back three or four years, and began at the sigmoid flexure of the colon and gradually extended, involving the bladder, the rectum, and the prostate. There was no fecal fistula into the bladder, but for a long time there was continuously more or less hæmorrhage into this viscus, causing great pain, and requiring the constant use of a flexible catheter. There was no vomiting except what might be ascribed to the use of opium. Dr. H. B. Sands saw this patient several times with me. Cachexia was not marked until a few months before death.

In the *third case* I did not suspect that the disease involved the colon; nor did Dr. Satterlee, who was the regular attendant. The patient was supposed to have cancer of the stomach and of the liver. There was persistent vomiting for many weeks, with great intolerance of food except that of the most bland, unirritating kind, given in small quantity. There seemed to be evidence of a tumor at the pyloric end of the stomach, but at the post-mortem examination this organ was not found to be involved. The cancer involved the sigmoid flexure of the colon, the peritonæum, the bladder, and the liver.

All three of these cases were characterized by very severe pain. There was a great difference in the comparative duration of the disease. In one case the first symptom dated back certainly not more than eight months before

* An abstract of remarks made before the New York Medical and Surgical Society, October 28, 1882.

death; in another it dated back three or four years. There was extreme emaciation in each case, coming on in the second case, however, only within a few weeks of the fatal termination. The first patient was sixty-one, the second sixty, and the third sixty-two years of age. Bamberger has recorded a case in which a woman fifty-seven years of age was first taken with vomiting and intense pain, etc., and he found a tumor of about the size of a pigeon's egg, not painful, in the right iliac fossa. Within four days the tumor had reached the size of the fist, and within four weeks the patient died of exhaustion.

I have notes of ten other cases of malignant disease that have come under my observation within the past ten years, involving either the ascending, the transverse, or the descending colon, and other parts, excluding the rectum. All these patients lived out of town, and I saw them only once or twice each, giving my opinion in a letter to their attending physicians. I requested in each of them that in the future I should be informed whether my diagnosis was correct or not. I received answers in regard to six, stating that my diagnosis was correct. Of the four others I have heard nothing. Had I made a wrong diagnosis, however, it is probable I should have been informed of the mistake.

It is a curious fact that, in every one of the thirteen cases of malignant disease of the intestines that I have known of during the past ten years, the disease occurred in men; in nine the part involved was the ascending or descending colon, in one the transverse; they were all patients over sixty years of age; each case was characterized by very intense pain. The German writers speak of pain as not being at all characteristic in these cases. I have frequently met with cancer of the uterus in which pain was either absent or due to some other cause. I have found this also to be true in some cases of cancer of the breast.

I have been asked if I had noticed any association between cutaneous disease and malignant disease of the intestine, the statement being made at the same time that certain authors had observed it; and I have likewise been reminded that, in the three cases related, one of the patients suffered from psoriasis, and the two others from eczema, one of them for many years. I have never had a case of primary cancer of the rectum in a woman, and only five cases in men, none of whom were my own patients. Pain was not a characteristic symptom in any one of them.

In this connection I will mention two cases of primary cancer of the omentum in women. In the *first case*, when I saw the patient she was in the most intense suffering. The bladder and the bowels had not been evacuated for three days. On examination, I found a tumor filling the pelvic cavity, the nature of which I could not determine. I was unable to feel the uterus. I then put the patient under the influence of chloroform, placed her in the knee-chest posture, and succeeded with some difficulty in introducing the whole hand into the rectum. After pushing the entire mass above the brim of the pelvis, I introduced a catheter and drew off a large quantity of water, but I was still unable to decide positively what the nature of this tumor was. I was satisfied, however, that it was not the uterus, not the ovary, and probably not the kidney. The

patient had a similar attack about one year after, in London, when certain physicians saw her whose names I do not remember; and then Mr. Spencer Wells was called in, who, without knowing anything of her previous history, adopted the same procedure which I had resorted to before. Sir William Jenner, who was associated with Mr. Wells afterward, also made a careful examination, but neither of those gentlemen was able to determine the character of the tumor absolutely. Mr. Wells, with the concurrence of Sir William Jenner, then made an exploratory incision, and found cancer of the omentum. After that the lady was comparatively comfortable, but a railway journey brought on a peritonitis, from which she died a few weeks afterward. At the autopsy there was found to be cancer of the omentum, which also involved the ovaries and adjacent tissues.

In the *other case* the disease had also involved the liver and the peritonæum. In both cases there was ascites. The first patient was tapped eight or ten times before death occurred. In the first three cases of cancer of the intestine, already mentioned, there was no abdominal effusion, which is opposed to the statement made in the books, that cancer of the intestine is very generally accompanied by ascites. I have, however, seen ascites largely developed in cases of cancer in which the disease involved the rectum, the prostate, and other adjacent structures, and I once made the diagnosis of malignant disease in the pelvic cavity mainly because the patient had phlegmasia dolens.

SUTURES IN GYNÆCOLOGICAL OPERATIONS.

By JAMES B. HUNTER, M. D.,

SURGEON TO THE WOMAN'S HOSPITAL, ETC.

For many years past I have been accustomed, in common with the other surgeons of the Woman's Hospital, to the use of silver wire in nearly all the ordinary gynæcological operations. The wire used has been manufactured of chemically pure silver, the sizes being Nos. 26, 27, and 28. No. 26 has been used for operations on the perinæum; 27 for the cervix; and 28 for fistulæ and the more delicate operations. In closing the abdominal wound after ovariectomy I have always used silver wire, No. 26, and have generally seen it used, though some operators prefer the ordinary carbolized silk, which seems to answer perfectly for that purpose. From time to time I have experimented with sutures of other material than silver for the perinæum and cervix. Catgut I have not found always reliable. Besides yielding before union was perfect, it was sometimes, no matter how carefully prepared, liable to be followed by slight ulceration. Silk thoroughly carbolized answers fairly for operations on the perinæum, vagina, and cervix, but it has a tendency, especially in subjects who are anæmic, or imperfectly nourished, to cause ulcerative action in its own track. I have closed a lacerated perinæum with common linen thread, carbolized at the time it was used, and obtained perfect union without the slightest ulceration. I have often used ordinary twisted silk for the perinæum, and have occasionally used it for the cervix, with satisfactory

results in both. In closing a perinæum immediately after laceration I always prefer the silk suture. It causes no pain afterward; it is quite firm enough to keep the recently torn surfaces in apposition; and its removal causes the patient no discomfort. These remarks apply to the partial rupture of the perinæum; where the sphincter ani is torn, I should give a decided preference to silver over any other material for sutures. I have lately done several operations on the perinæum and cervix with what is known as silk-worm gut, as prepared for fishing purposes, which I had seen Dr. Emmet use for closing the abdominal wound after ovariectomy. It is a fine, transparent suture, ties easily and securely, and can be withdrawn with ease; but it has a greater tendency to cut than either common silk or silver wire, and, even when carefully carbolized, does sometimes cause slight ulceration. This tendency to cut is probably explained by the fact that a transverse section of this suture shows it to be very irregular in shape. It is occasionally round, but generally either flat or triangular, with sharp cutting edges. It is rendered somewhat softer by soaking in warm water, but very hot water roughens its surface and makes it unpleasant to work with. From my present experience with it I think its employment should be limited to cases where there is not much tension on the sutures, and where it is desirable to use a suture of small caliber. It has the advantage of causing little or no pain while *in situ*, or while being withdrawn.

The advantages of silver wire over all non-metallic sutures are:

That it is perfectly clean and aseptic.

That by its rigidity it gives a desirable support to the parts while union is taking place.

That, being secured by twisting, it may, with the utmost nicety, be made to exert the precise degree of pressure desired, and may be loosened if it has been too tightly twisted.

That, by molding it with the point of a tenaculum at the points of entrance and exit, the exposed border of the suture may be made a straight line, from which the wire penetrates the tissues at right angles, and is, therefore, less likely to cut at those parts. Before thus bending the suture it is a circle, as in Fig. 1. Afterward it has the form shown in Fig. 2. The latter form gives a better support to the

FIG. 1.

FIG. 2.

parts, especially in operations on the perinæum and vagina. It also presents itself in such a manner as to be easily seen and reached by the scissors when it is necessary to remove the sutures.

A minor objection to the silver wire is its expense; but

even if this were not more than compensated for by its advantages, it is always practicable to employ wire of soft copper, silver-plated, which answers very well, and is much less expensive. I once had some wire made of pure gold, and used it in place of the silver. It was no better in any respect than that made of silver; and, after a pretty large experience with various sutures, I consider silver the best material for use in nearly all gynecological operations.

2 EAST THIRTY-THIRD STREET.

CASE OF ISCHIO-RECTAL ABSCESS CURED WITHOUT THE FORMATION OF A FISTULA.

By CHARLES B. KELSEY, M. D.,

SURGEON TO ST. PAUL'S INFIRMARY FOR DISEASES OF THE RECTUM.

The patient, a professional man, aged thirty-seven years, had been suffering for several years from large internal hemorrhoids which bled freely. For some weeks before sending for me he had been under the care of an irregular specialist, who had been following out some plan of local treatment for this condition, the nature of which the patient did not understand. Although there was some decrease in the amount of blood lost, his general condition became far from satisfactory. Though naturally a large, healthy man, and accustomed to hard mental work and abundant exercise, he began to suffer from lassitude, loss of appetite, and emaciation. Finally, a hard mass was felt in the right ischio-rectal fossa, which caused him a good deal of pain, and after this had lasted five days he sent for me.

Examination.—A hard, brawny, painful swelling completely filled the right fossa. The skin over it was red and hot, but there was no fluctuation. There had been a chill, some fever, and complete loss of appetite, with a good deal of rectal tenesmus.

Operation.—The patient was etherized, and a deep incision made into the swelling. Although the cut was made over the most prominent portion of the mass, it failed to reach pus, being too far out upon the buttock. A longer, straight knife was again entered within half an inch of the margin of the anus, and carried steadily upward, parallel with the bowel, about four inches. The blade was turned in its track occasionally as it was entered, to allow of the escape of pus as soon as it was reached, but none appeared till the depth mentioned was arrived at. After pus was found, the knife was withdrawn, making an incision fully three inches long at the surface, in an antero-posterior direction. Into the opening thus made the finger was passed till it reached the abscess cavity, and all partitions were broken down. This part of the work was done very thoroughly, and the original incision was made still longer, so that future burrowing might be avoided. A solution of carbolic acid was then injected into all parts of the wound, and the cavity was dressed with lint soaked in carbolized oil (1-12). After this the sphincter was dilated, and several large hemorrhoidal tumors were removed. The dressing thus introduced was allowed to remain undisturbed for three days, when it was removed and a similar one replaced, after a thorough washing out of the wound and the introduction of

the finger into all parts of it. The patient was kept strictly in bed, and the bowels confined for one week with medicine, at the end of which time they moved easily and painlessly after a dose of salts.

The operation was performed July 5th. On September 15th he was entirely well, the wound having completely closed. This time might have been shortened a good deal had the patient not been obliged to be up and about his business during the latter part of the time the wound was healing. He was seen two months later, and was "as well as he had ever been in his life."

This case illustrates exceedingly well several points in rectal surgery. As to the causation of the abscess, it can not be positively stated whether it was the result merely of his general depreciated condition, whether it was the result of direct injury while undergoing some secret treatment for hæmorrhoids, or whether it was purely idiopathic. Whatever its cause, the condition was one which certainly would have ended in a deep fistulous track opening high up into the rectum, above the internal sphincter, had not this particular operation been performed. It is safe to say that had this abscess been left to its own course, or had it been opened in the usual way—that is, by making an incision just large enough to fairly evacuate its contents—the subsequent history of the case would have been entirely different. The fistula which would have resulted would have required a deep incision, involving both sphincters, for its cure, and such an incision is exceedingly apt to be followed by incontinence of feces. The case is one of a class which, left to the course of nature, often work irreparable injury—injury which may render the patient's whole subsequent life one of suffering in spite of any future surgical procedures—and yet, if treated promptly and efficiently, may be brought to a very happy termination. It is the kind of case in which a single day's delay may be ruinous to the interests of the patient, and for that reason alone I have thought it worthy of special note.

"THE MADISON," 25 MADISON AVENUE.

Clinical Reports.

WOMAN'S HOSPITAL.

Reported by ANDREW E. CURRIE, M.D.

(SERVICE OF DR. THOMAS ADDIS EMMET.)

CYSTITIS OF LONG STANDING.

M. B., unmarried, a native of Germany, forty years of age, was transferred to Dr. Emmet's service from the service of another surgeon in the Woman's Hospital in the early part of the summer of 1881. She began to menstruate at sixteen years of age; is regular, the quantity is normal, the duration is from two to three days. Before the flow is established she suffers from headache and backache. There is profuse hæmorrhage, which is very painful, and the pain in her bladder is intense. This is her history upon entering the hospital. She was placed upon the regular treatment, viz., vaginal injections of carbolic lot water twice daily, and also received extra diet and anodynes as required. The latter were called for rather frequently, especially

at night. The first operative procedure consisted in making an artificial fistula in the urethra, the edges of the vaginal and urethral mucous membranes being stitched together on either side, thus preventing the escape of the fistula, and forming what Dr. Emmet calls a *button-hole fistula*. This procedure did not give the relief which was anticipated. After being transferred to Dr. Emmet's service, a *button-hole catheter* was introduced, which she continued to wear with comfort for some time. September 20, 1881, the observation made was that the edges of the fistula were thickened, and a forty-grain solution of nitrate of silver was frequently applied. October 19th, the catheter was removed. October 24th, Thomas's anteversion pessary, *reversed*, was inserted into the vagina, to keep the edges of the fistula apart. November 15th, the excess of mucous membrane in the urethra was drawn down, and, after being freshened, was stitched to the edges of the fistula. The parts united, but the patient continued to suffer. December 12th, a further removal of hypertrophied mucous membrane of the bladder was made. December 27th, the bladder being, to all appearances, in a healthy condition, the fistula was closed. The attempt was unsuccessful, as were similar attempts February 2d and March 17th. May 2d, a fourth attempt was made, and was entirely successful. The patient remained in the hospital until June 5th, and, as there was then no evidence of a return of the cystitis, she was discharged.

Remarks.—Here is a case of a disease which is usually both intractable and very painful, which was, to all appearances, cured. The woman was of an hysterical temperament, and bore pain badly. There was no doubt in the matter, therefore, when she said that she was relieved. The elements in bringing about the good result were chiefly three: 1. The rest afforded to the bladder by the fistula. 2. The dilatation of the urethra by the catheter, which was worn a long time. 3. *Probably* the stimulus to the circulation and nutrition of the parts produced by the several operations. Why four operations should have been necessary to close the fistula we can not say.

VENTRO-VAGINAL FISTULA.

Mrs. E. McC., aged forty-one, a native of Scotland. This case was reported in vol. xxxiv of this journal for 1881, p. 175, as far as the conclusion of the second operation, which had failed in closing the fistula entirely. The patient's paralysis had disappeared, her general health had become excellent, and the suspicious symptoms of pyelitis, or of inflammation of the ureters, no longer threatened. October 11th, Dr. Emmet closed the small fistula which remained. The tissues were now so much improved in their tone that it was strongly hoped that a favorable result would follow the operation, which was borne by the patient without an anæsthetic. It was a failure, however, as were also other attempts made December 1st, January 24, 1882, and February 28th. March 28th, after preparing the edges of the fistula, two incisions upon the lateral walls of the vagina were made, with the view of relieving the tension of the sutures with which the wound was closed. This expedient also failed. The edges of the wound seemed to have lost their vitality, and until the next operation they received occasional applications of solid nitrate of silver. May 16th the operation was repeated, and incisions were made parallel to the line of sutures, in hope of relieving the tension. May 30th the sutures were removed, and the wound by this time had healed. The sigmoid (Sims's) catheter was allowed to remain yet a day or two in the bladder. (It will be remembered that it is the custom to use this catheter, which is made of block-tin, sigmoid in shape, after fistula operations at the Woman's Hospital, so that the urine drains away as soon as it reaches the bladder. The bladder, therefore, can not become distended, and weaken the line of

union.] June 18th, the bladder holds water, but is very irritable and painful. Washing it out daily with a warm saturated solution of boric acid allayed the trouble in a few days. June 29th, as the hospital was about to be closed for the summer, she was discharged.

LACERATION OF THE CERVIX UTERI; CELLULITIS AND CYSTITIS.

Mrs. C. H., aged thirty-four, a native of Germany. She has been married nine years, has had four children, and one miscarriage. She has been sick since her last labor, suffering from leucorrhœa and pains in the bladder. Occasionally catheterization has been necessary. She entered the hospital September 14, 1881, and began at once to be treated with hot vaginal douches, and applications of Churchill's tincture of iodine to the vaginal vault three times weekly. September 26th, the uterine canal was curetted, and a quantity of fungosities was removed. [This operation is usually done *under ether*, as it is apt to be very painful.] February 14, 1882, the cellulitis had disappeared, and Dr. Emmet closed the laceration of the cervix to-day. The operation was not entirely successful; there had been some sloughing upon the left side of the cervix. May 1st, the patient is exercising freely out of doors. Her chief complaint now is in connection with her bladder. May 8th, she has been ordered to drink a pint of infusion of triticum repens daily. May 26th, the bladder is still troublesome. It is washed out daily with a solution of sulphate of zinc, six grains to the ounce. May 31st, she was discharged greatly improved.

Remarks.—This case is interesting for various reasons. We see illustrated here the value of the *preparatory treatment*, as it is called by Dr. Emmet, in getting rid of that painful trouble, pelvic cellulitis. Even so skillful an operator as Dr. Emmet fails of success sometimes in his operations upon the cervix. This should encourage those whose first attempts are not followed by the results which they had hoped for. If the operation wound does not heal by first intention, which is the rule, the next best thing is to bring about union by frequent applications of a forty- or sixty-grain solution of nitrate of silver. The bladder complication is interesting, as introducing therapeutic elements additional to those given in the preceding cases.

Book Notices.

On the Morbid Conditions of the Urine dependent upon Derangements of Digestion. By CHARLES HENRY RALFE, M. A., M. D., Caius College, Cambridge, Assistant Physician to the London Hospital, etc. London: J. & A. Churchill, 1882. Pp. viii-148.

The title of this book is in some degree a misleading one, since, instead of laying chief stress upon laboratory examinations of morbid urines, Dr. Ralfe has really given us an excellent clinical treatise on various forms of dyspepsia, with scarcely a word of analytical methods; a treatise addressed rather to the practicing physician than to the student of chemical manipulations.

An introductory chapter considers the sources of acid in the body and the channels for its elimination, leading to a classification of acid dyspepsias into those arising from over-secretion of hydrochloric acid; those from fermentative changes generating organic acids; and a third category wherein both factors combine—the excess of hydrochloric acid arresting digestion, and thus indirectly inducing the formation of lactic, acetic, and butyric acids. The alkalinity of the blood, despite the introduction of acid from without and its greater generation within the body, is ascribed chiefly to the preponderance of sodium

bicarbonate, which, though an acid salt, has an alkaline reaction, but also to the conversion of the salts of the vegetable acids into alkaline carbonates. To the withdrawal of these vegetable acids is exclusively imputed the pathogeny of scurvy, some other alkaline salts (principally the alkaline phosphates) being retained instead of excreted. In four places we find it laid down as an indisputable fact that the sole cause of scurvy is the deprivation of succulent fruits and vegetables—a statement which needs further consideration in view of the observations of Arctic explorers, which tend to show that fresh food of any kind, animal as well as vegetable, is an efficient antiscorbutic, as exemplified most markedly in the case of the Esquimaux, whose food is strikingly deficient in the matter of fruits and vegetables.

Chapter II treats of dyspepsia usually associated with an acid condition of urine, and gives certain data toward a differential diagnosis between the acidity of over-secretion and that of fermentation, the urine in the former case showing, in general, increased acidity with deposition of uric acid and urates, though subject to great variations in this respect from time to time, while in the latter case there is diminished acidity, or even alkalinity, of the urine, with a tendency to deposit oxalates or phosphates. It is, however, admitted that either of these forms of acid dyspepsia may give rise to the other, and that in the not infrequent instances where both coexist it is difficult to determine which was the originating cause, or which is the preponderating condition, the latter being only discoverable by ascertaining "the nature of the acid present in the vomit." But, as we are expressly told that in fermentative dyspepsia vomiting is of rare occurrence, the test above mentioned loses some of its practical value. In the author's etiology of over-secretion of acid, malaria plays a part second only to that of gout.

Flatulent dyspepsia, usually associated with neutral or alkaline reaction of urine, is considered in Chapter III. Here urinary alkalinity is imputed solely to excessive elimination of the carbonates of sodium and potassium, arising from three causes: "General debility and the feebleness with which the respiratory act is performed, leading to the accumulation of carbonic acid in the system"; diminished secretion of bile, which is the chief secretion by which alkaline salts are removed from the body; and the oxidation of the acids formed by fermentative changes into carbonic acid, which forms carbonates with the bases of the alkaline oxides, and thus increases the alkaline-ness of the blood.

Chapter IV is devoted to derangements associated with deposits of uric acid, and here the author takes issue with many pathologists as to the origin and significance of this deposit. He believes that "the probable antecedents of uric acid in the blood are partly the kreatin formed in muscle and elsewhere, and partly the leucin and other like bodies formed in the alimentary canal," and doubts if uric acid is to any extent a measure of defective oxidation of albuminous substances, or, indeed, if it bears any definite relation to uric acid. He ascribes a deposit of uric acid from the urine or in the tissues rather to its insolubility than to its excessive production in the system, and refers its precipitation chiefly either to concentration or acidity of the urine, or to its accumulation in the urinary passages, so that a considerable discharge of it "does not represent the amount separated from the system within a period of twenty-four hours." He thinks, however, that a more or less persistent excess of uric acid with high specific gravity, but undiminished quantity of urine, "is a prelude to some serious organic mischief"—often strumous or tubercular. Of the relation of the "uric-acid diathesis" to gout he is more than skeptical; and he does not attach much importance to the occasional deposits of uric acid in diabetic subjects. The influence of an excessive animal diet in inducing

gout is attributed rather to increased tissue metabolism, leading to degenerative changes, than to augmented production of uric acid; and the arthritic agency of alcoholic beverages is assigned almost wholly to the sugar which they contain, a secondary rôle, however, being played by their percentages of acids and acid salts. Thus it will be seen that the doctrine of "lithæmia" finds no place in the philosophy of the author, who regards uric acid "as a consequence, and not a cause, of the manifold disorders to which it has been said to give rise."

In the following chapter the origin and significance of oxalic acid deposits are discussed, and the diversity of opinions on this subject, as taught by different writers, is explained by the statement that such deposits occur in two distinct classes of urines: "The one of deep yellow, or orange color, of high specific gravity, usually containing an excess of urea and phosphoric acid, and turbid with mucus and urates," in which case oxalate of lime may be formed, after emission, from decomposition of uric acid and urates, or from oxidation of pigmentary matters and mucus. "The other pale, of a citron-yellow or greenish hue, of medium specific gravity, and perfectly clear except at the bottom of the urine-glass, where a slight cloud of mucus is collected, and in which deposited oxalates will be found," associated here with the dyspepsia and hypochondriacal symptoms belonging to Guldberg Bird's typical "oxaluræ," and arising, in the author's estimation, from excessive fermentative production of lactic and butyric acids, and their imperfect reduction into carbonic acid, so that "the intermediate acid—oxalic—appears in the urine in combination with lime." Of course, the various extraneous sources of oxalic acid, from food or drugs, are taken into account. In cases of oxalic calculi it is observed that the acid may have its origin in the mucus of the urinary passages, indicating a local rather than a systemic derangement.

The final chapter deals with the very uncertain problem of phosphaturia; not the mere presence of crystals of triple phosphate from ammoniacal fermentation of the urea, due to local vesical catarrh, but the persistent excessive elimination of phosphoric acid in cases attended by grave constitutional depression and polyuria. After reviewing the unsatisfactory literature of this subject, the author feels only warranted in expressing the avowedly vague conclusion "that increased excretion of phosphoric acid is met with in those states of the system which we characterize as 'nervous,' and that it is often met with accompanying or preceding diseases in which disorder of nutrition is usually well marked."

An appendix contains some original observations on the effects of bicarbonate of potash upon the acidity of the urine, demonstrating that "the administration of an alkaline bicarbonate on an empty stomach increases the acidity of the system, while its administration after a meal diminishes it." Clinical remarks on the symptomatology and treatment of the different morbid conditions described are given in their respective chapters, and will doubtless possess most interest for the average practitioner.

Despite a slovenly style, marred by repetitions, by ambiguity, and sometimes by grammatical solecisms, Dr. Ralfe's book contains more food for thought—perhaps we may add more material for debate—than most of the recent issues from the medical press. Some of his speculations are rather in advance of our demonstrable knowledge of physiological chemistry; but every page shows him to be a clear reasoner and close observer, whose views are worthy of consideration.

A Treatise on the Practice of Medicine, for the Use of Students and Practitioners. By ROBERTS BARTHOLOW, M. A., M. D., LL. D., Professor of Materia Medica and General Therapeu-

tics in the Jefferson Medical College of Philadelphia, etc. Third edition, revised and enlarged. New York: D. Appleton & Co., 1882. Pp. xx-918. [Price, cloth, \$5; sheep, \$6.]

We congratulate Professor Bartholow most heartily on the appreciation with which the profession have received his very compact and straightforward text-book. That this reception has not been due to any artificial impression produced by laudatory reviews is shown by the fact that the second edition was called for within a month after the first issue of the book, comprising three thousand copies—at a time, therefore, that must have antedated any such notices. The continued popularity of the work must, as a necessary result, be doubly gratifying to the author. Indeed, so far from his having been helped along by unmerited praise, his energetic utterances concerning "therapeutic nihilism" rather led his early reviewers to caution their readers touching his undue confidence in medication. In face of this criticism, Dr. Bartholow has stood sturdily to his statements, and now feels fortified, as he tells us in his preface, by letters received by him from various correspondents, giving their favorable experience with the methods of treatment laid down in the book. Still more to his credit is it that, while expressing his gratification at this state of things, he calls upon his readers to make known any opposing experience that may have fallen to their lot.

There is now no question, it seems to us, that for a book giving a succinct guide to pathology and therapeutics, as applied to the actual practice of medicine, Dr. Bartholow's is unexcelled. It seems to embody a continuation of the good work which the late Dr. Anstie began, of rousing the English-speaking profession from the apathy into which it had fallen in regard to therapeutics, while at the same time it presents the present state of our knowledge of nosology, pathology, and diagnosis in a readable and telling way, wasting no space in padding, but going straight to the practitioner's needs. Of such books there are too few, and we trust that Dr. Bartholow will frequently be called upon to revise and extend his work.

Materia Medica and Therapeutics. Inorganic Substances. By CHARLES D. F. PHILLIPS, M. D., M. R. C. P., late Lecturer on Materia Medica and Therapeutics at the Westminster Hospital Medical School. Edited and adapted to the United States Pharmacopœia by LAWRENCE JOHNSON, A. M., M. D., Lecturer on Medical Botany, Medical Department of the University of the City of New York, etc. Two vols. New York: William Wood & Co., 1882. Pp. xv, 298; vi, 340. [Wood's Library of Standard Medical Authors.]

This work concludes the treatise, of which the first part was published in the same series in 1879. Among the several really excellent works which appeared in that initial series we must confess that Dr. Phillips's book, devoted to a consideration of those drugs which are derived from the vegetable kingdom, made but a sorry show, so that the reader would have been quite content that it should end then and there. But we are pleasantly disappointed in this second part, which takes up inorganic substances. Aside from the improved binding and typography, the volumes themselves are more thorough and readable. Although it can not be regarded as in any sense an original work, and although it is too diffuse for the ordinary reader, the author is right in stating, as he does in his preface, that pharmaceutical chemistry, materia medica, and therapeutics should be incorporated in a natural sequence, instead of being considered separately in treatises devoted to those subjects.

At the beginning of each section there is a preliminary statement of the chemistry of each drug, then follows its physiological action, including the toxicology, and finally its therapeutic appli-

caution. There are additional paragraphs on idiosyncrasy, and on synergists and antagonists, the latter being closely modeled after Bartholow. Were we to criticise the work as a whole, we should say that the author might have condensed his discussions of experimental physiology by confining himself more to important investigations and devoting less space to side-issues. The therapeutical part of the book is altogether too prolix, and the reader can not but contrast it with the brief, conservative utterances of Wood. Doubtless our English brethren have more faith in the efficacy of drugs than we, for how otherwise could Dr. Phillips have given four pages to a consideration of the sovereign virtues of calcium sulphide?

There is a strong suggestion of Ringer in this chapter. Gynecologists in this country will remark with surprise the long list of remedies stated to be of value in their department. In five instances uterine fibroids have disappeared under Dr. Phillips's observation by the use of injections of iodine. Even ovarian cysts diminish in size with five- to twenty-grain doses of potassium bromide (!). We have not been so fortunate in the medicinal treatment of pelvic troubles.

We have not the space in which to consider this work in detail, which is to be regretted, as it contains some excellent chapters. We commend in particular, as being thorough and instructive, those on iodine, water (in which is a judicious statement on balneology and its value), arsenic, and mercury.

The paragraphs on preparations and dosage are placed at the end of each article, and are not arranged as clearly as we could wish. The method of Bartholow seems to be preferable. Neither do we see any advantage in substituting the Arabic for the usual Roman method of notation. An entire absence of reference to the metric system is noticeable, since most modern treatises on therapeutics defer to the growing idea that this is to be the system of the future.

In conclusion, it may be said of Dr. Phillips's book that, while it does not fill any long-felt vacuum in this department of medical literature, it is clear and readable.

Essentials of Vaccination; a Compilation of Facts relating to Vaccine Inoculation and its Influence in the Prevention of Small-pox. By W. A. HARDWAY, M. D., Professor of Diseases of the Skin in the Post-Graduate Faculty of the Missouri Medical College, St. Louis, etc. Chicago: Jansen, McClurg & Co., 1882. Pp. 146. [Price, \$1.]

For a long time the profession in this country have felt the need of a concise manual of the practical points connected with vaccination, a subject concerning which there are few who are not likely to profit by such a book, combining the essentials of the practice of vaccination with so much of the underlying facts and theories in regard to the varioliform diseases as may be required to fix the practical part of the matter in their minds. It was on all accounts desirable that such a task should be undertaken by one well versed in dermatology, and at the same time well informed as to the work that has been done of late years by those who have been engaged in the experimental study of vaccination, particularly animal vaccination. Precisely such a person is Professor Hardway, and, in our opinion, the profession is indebted to him for a most excellent little work. Not that we agree with him on all points; but we can say, without the slightest reserve, that his book comes as near to a faultless presentment of the subject with which it deals as is possible in the present state of our knowledge.

The ten chapters of which the book is made up treat respectively of the history of vaccination, of variola in animals, of the nature of vaccinia, of vaccinia in the human subject, of abnormal modifications and complications of vaccinia, of reac-

cination, of the merits of different kinds of vaccine virus, of the methods of obtaining and storing vaccine virus, of the operation of vaccinating, and of the objections to vaccination. Under each of these heads the author displays a ripe knowledge of the subject, a simple and attractive style of presenting its salient points, and an intelligent appreciation of what has been done by others in the same field. The book certainly deserves to be read by every member of the profession, and we trust that it will meet with a wide circulation.

Diseases of Memory: an Essay in the Positive Psychology. By TH. RIBOT, Author of "Heredity," etc. Translated from the French by WILLIAM HUNTINGTON SMITH. New York: D. Appleton & Co., 1882. Pp. 209. [International Scientific Series.]

In this volume the author presents for our consideration two forms of memory. First, organic memory, in which actions are reproduced without the element of consciousness. Second, psychological memory, or that in which the element of consciousness is indispensable.

Although the writer's views are interesting, and are seductively expressed, we are hardly prepared to agree with him in the theory that memory may be organic. The classification of this form of memory embraces all those unconscious acts which individuals perform while suffering from certain forms of epilepsy, or else under the influence of sleep, and also all co-ordinate muscular movements, such as are made in walking, running, swimming, etc.

This theory seems to us to be untenable unless the seat of memory may be supposed to reside, to a certain extent, within the cerebral ganglia and spinal cord—a supposition which the author does not admit for a moment. Motor impulses to all unconscious and to all so-called automatic impulses must originate in the cortex of the brain. After the impulse is once generated the unconscious movements may be, and are, continued by the action of the cerebral ganglia and spinal cord without the cortex participating to any extent whatever. That this is the case with horsemen who maintain their equilibrium in the saddle while asleep, and with individuals when running, walking, etc., is undoubted. The explanation of those cases of epileptic vertigo in which persons perform certain apparently unconscious actions has never been satisfactorily stated. The author, however, is of the opinion, as expressed in the first part of his chapter on general amnesia, that in the majority of these cases a very weak form of consciousness does exist. Thus does the writer himself exclude the epileptic variety of organic memory from his classification.

With this exception, the monograph is excellent. As the author states in his preface, "The phenomena of memory have never been investigated from a pathological stand-point." This he has successfully attempted, and the ensuing chapters are not only exceedingly interesting, but convey their meaning in a clear and concise manner.

Essays on the Floating Matter of the Air in relation to Putrefaction and Infection. By JOHN TYNDALL, F. R. S., etc. New York: D. Appleton & Co., 1882. Pp. xix+338.

PERHAPS no one man has done more to put antiseptic surgery on its present firm basis than Professor Tyndall, and from this little work the reader may gain a clearer insight into the fundamental facts on which that great advance in our art rests than from any other single book with which we are acquainted. The importance of thus getting at the real philosophy of the antiseptic system of treatment can not be over-estimated, for he who best understands it will most successfully carry out its practical application.

Florida for Tourists, Invalids, and Settlers, etc. By GEORGE M. BARBOUR. With map and illustrations. New York: D. Appleton & Co., 1882. Pp. 310.

WHILE Mr. Barbour's book is not objectively, or even largely, sanitary in its scope, it yet gives such an intelligible picture of Florida as a health resort that its perusal can not fail to remove up the doubts that a physician may entertain as to the propriety of recommending a sojourn in that State to the particular invalids who may come to him for advice. And the latter themselves will find in it many valuable hints of just that sort that is needed by an invalid traveler. It is most agreeably written, and with an evident candor and freedom from bias that commend it at once.

The Medical Digest, or Busy Practitioner's Vade-Mecum. Being a Means of readily acquiring information upon the Principal Contributions to Medical Science during the last Thirty-five Years. By RICHARD NEALE, M. D. Lond., etc. Second edition. London: Ledger, Smith & Co., 1882. Pp. 643-lxxxii.

This is an analogous work to our American "Index Medicus," but much less comprehensive than the latter, for, instead of abstracting from all current literature, it limits itself to a small number of publications, chiefly English. We said it was analogous to the "Index Medicus," which is not strictly correct, as in addition to the reference there is, in many cases, a brief digest of the article. The author has been patiently continuing this habit of noting down articles of importance for thirty-five years, giving an example which it would be well for others to follow. In so far as the book goes, it is a very useful one.

A Practical Laboratory Course in Medical Chemistry. By JOHN C. DRAPER, M. D., LL. D., Professor of Chemistry in the Medical Department, University of New York, etc. New York: William Wood & Co., 1882. Pp. vi-71.

This is another of the condensed laboratory text-books of which so many have lately been issued, and, judging from a somewhat superficial examination, it would seem, in point of convenience and fullness, to be rather in advance of its competitors. The name of the author is a guarantee of its accuracy, and the binding and make-up are good.

Regional Surgery, including Surgical Diagnosis. A Manual for the Use of Students. Part I. the Head and Neck. By F. A. SOUTHAM, M. A., M. B. Oxon., F. R. C. S. E., Assistant Surgeon to the Manchester Royal Infirmary, etc. London: J. & A. Churchill, 1882. Pp. xvi-229.

This book deals with the regional surgery of the head and neck alone, being the first of a series of three proposed volumes. It covers, in successive chapters, tumors of the scalp; surgical diseases of the scalp and cranium; injuries of the head; surgical affections of the face, nose, and lips; the various diseases of the jaws, teeth, mouth, tongue, palate, gums, tonsils, pharynx, and esophagus; the abnormal states of the lachrymal and auditory apparatuses demanding surgical treatment; and the surgical affections and injuries of the neck.

It will readily be seen that such an extensive field can not be covered in much detail in a volume of so small a size. It has surprised and gratified the reviewer, however, to find so much valuable matter compressed into this small compass. The hints embodied in the work are well chosen, and are clearly impressed upon the reader. The method adopted of giving marginal references to the text greatly assists in rapid reference, and will add to the value of the book, especially with those who

have little time to devote to systematic reading. The tables of differential diagnosis occasionally incorporated in the text of the work remind us of an American work upon surgical diagnosis which is constructed largely upon that plan. Such tables have a double advantage over simple descriptive text—viz., they afford a given amount of information in the smallest possible space, and, in addition, assist the memory of the reader by connecting descriptive pictures of the diseases having points of resemblance. We heartily commend this work, and believe that when completed it will prove a valuable addition to the library of any physician.

Questions on Human Anatomy. By SAMUEL O. L. FOTTER, M. A., M. D., etc. With sixty-three illustrations. Philadelphia: P. Blakiston, Son & Co., 1882. Pp. 139. [Price, \$1.]

THIS work is the first of a series of eight volumes now in preparation. The series, as a whole, is supposed to exhaust the more important points treated of by the incumbents of the seven chairs of our medical colleges. The work is arranged in the form of questions and answers, intended to be used for self-examination, and to supply the demand now filled by quiz-masters. We do not think that any book of this kind can do what a supervising instructor accomplishes (if he be competent), but such aids may often be used by students to advantage, provided they are not abused. The danger is that students too often confine themselves to such cram-books (to the exclusion of standard works), and thus become superficial in their knowledge. The work under consideration is a good one of its kind.

BOOKS AND PAMPHLETS RECEIVED.

Nerve-Vibration and Excitation as Agents in the Treatment of Functional Disorder and Organic Disease. By J. Mortimer Granville, M. D. London: J. & A. Churchill, 1883. Pp. 128.

Microbes in Fermentation, Putrefaction, and Disease. Paper read before the Philosophical Society of Glasgow, December 14, 1881. By Charles Cameron, M. D., LL. D., M. P. London: Baillière, Tindall, and Cox, 1882. Pp. 32. [Price, 1s.]

The Termination of the Nerves in the Liver. By M. L. Holbrook, M. D. Reprinted from the Proceedings of the American Society of Microscopists. Pp. 95 to 100, inclusive.

The Structure of the Muscles of the Lobster. By M. L. Holbrook, M. D. Reprinted from the Proceedings of the American Society of Microscopists. Pp. 131 to 138, inclusive.

London Water Supply. Report, etc. No. xxii.

Transactions of the Medical Society of the State of New York for the year 1882. Pp. 474-17.

Suprapubic Lithotomy. The High Operation for Stone—Exposition of the Principles of the Operation and the Apparatus. By William Tod Helmuth, M. D., Professor of Surgery in the New York Homeopathic Medical College, etc. Illustrated with eight lithographic plates and numerous engravings on wood. New York and Philadelphia: Boericke & Tafel, 1882. 4to, pp. 93. [Price, \$4.]

Old School Medicine and Homeopathy. A reprint from the "North American Review," June, 1882, being a reply to Professor Palmer's article in the March number, entitled the "Fallacies of Homeopathy." By J. W. Dowling, M. D., Professor of Physical Diagnosis and Diseases of the Heart and Lungs, New York Homeopathic Medical College, etc. New York: C. T. Hurlburt, 1882. Pp. 26.

An Inquest on Medical Cases, and a Memorial to the Medical World of America. The Minutes of the F. P. S. Proceedings as to the Death of the late Mr. S. R. Aitken, with Editorial Comments and Correspondence. Reprinted from the "English Observer." Colombo, 1882. [From Dr. J. L. Vanderstraeten.]

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 20, 1883.

MASSACHUSETTS IDIOTS AND LUNATICS.

In his inaugural message the new Governor of Massachusetts alludes to the provisions made by that State for the care of the idiotic and the insane, or rather to the methods by which those provisions are carried out, in terms which indicate a versatility ready to busy itself with almost any problem that man may be called upon to ponder, and, furthermore, to solve it offhand.

"When," says General Butler, "the State shall have sufficiently educated every bright child within its borders, it will be time enough to undertake the education of the idiotic and feeble-minded. I submit," he continues, "that this attempt to reverse the irrevocable decree as to 'the survival of the fittest' is not even kindness to the poor creatures who are in this school. Give them an asylum, with good and kind treatment, but not a school. The report from that school shows that none of its pupils have been made self-supporting by its teachings. The report further shows that those in whom some spark of intelligence has been awakened have become so ashamed of their school that when they write to their parents they beg for paper and envelopes which have not its card upon it. That is, they have been educated simply enough to know of their deficiencies and be ashamed of themselves and their surroundings. We do not contribute to their happiness by giving them that degree of knowledge. A well-fed, well-cared-for idiot is a happy creature. An idiot awakened to his condition is a miserable one."

As we quote from a newspaper account, we are not sure that we are giving the Governor's English with precision; hence we forbear to comment upon it. Concerning the substance of what he says, however, there can scarcely be any inaccuracy. Barbarous as General Butler's view of this matter is, the fact on which he founds his argument must be gratifying in the extreme to the few devoted men and women who have labored to reclaim the idiotic. Surely it is no doubtful sign of success when an idiot is brought to such a state of intelligence as to be ashamed of himself for his deficiencies. Doubtless he is not made happy by this partial awakening of his faculties, but we take it that General Butler is very much in error if he supposes that the great object in attempting to reclaim idiots is to make them happy. We fail to see, too, any antagonism between such attempts and whatever "irrevocable decree" there may be as to the survival of the fittest. To carry his dictum to legitimate lengths, no time should be spent on dunces, but only the gifted should be educated, and the man who buried his one talent did the proper thing.

The Governor bewails the increase of insanity in the State,

and gives it as his impression in regard to establishments for the insane, both private and public, that "their doors open altogether too easily inward, and with too great difficulty outward." Evidences of the soundness of his position in this matter are often brought to light in the shape of felonies committed by those who had before been looked upon as harmless. For the "harmless chronic insane" the General suggests that provision be made on the cottage or family plan. He hints that psychiatry has not kept pace with the other branches of medicine, as shown by the decreasing percentage of cures effected among the insane for several years past. If the Governor's statements of facts are correct, there must be some factor to be taken into account beyond what appears, for we can scarcely entertain the supposition that the alienists of Massachusetts are materially behind their brethren elsewhere, and we are not aware that the practice of psychiatry is so defective in general.

DISTENSION OF THE FALLOPIAN TUBES.

DR. EMMET's specimens of dilated Fallopian tubes that Mr. Lawson Tait had removed by laparotomy, which were lately shown to the Obstetrical Society, and the considerable experience in Tait's operation that Dr. Thomas soon afterward recounted before the Academy of Medicine, in the form of the paper contained in our last issue, have awakened New York gynecologists to the frequency with which morbid conditions of the tubes may be found to play a leading part in giving rise to distressing symptoms, and in keeping up other pathological processes within the pelvis. They also show abundantly that much of Mr. Tait's work has not been of the shadowy character that has been imputed to it.

In view of the great activity that has been displayed of late years in the study of the diseases of the pelvic organs in women, and of the thoroughness with which physical methods of diagnosis have been applied to that study, it is not a little surprising that the facts now brought to light should heretofore, in great measure, have passed unrecognized. We can understand how it may have been in the past that a Fallopian tube, even largely distended, was so masked by surrounding exudate, matting adjacent structures together in one indeterminate mass, that its separate recognition by means of any or all of the methods of exploration applicable to the case was out of the question. Many of the specimens alluded to, indeed, were removed by abdominal incision on the strength of a diagnosis founded on so bold an inference as that disease of the tube must have been at the bottom of the rebelliousness to treatment shown in many cases in which the physical signs pointed to nothing more definite than an inflammatory deposit. Yet, in regard to some of them, the histories, in so far as concerns the state of the parts surrounding the tube, seem to show that it ought to have been possible to diagnosticate enlargement of the tubes with precision. That a mass shaped like a sausage, and often as large as a small sausage, not complicated with a bulky exudate or specially bound down by adhesions, should in repeated in-

stances escape recognition, can be imputed only to an omission on the part of the surgeon to take the condition into account in his mental catalogue of possibilities. Such an omission is not now likely to enter to any great extent into the list of obstacles to a diagnosis.

It seems probable that the general pathologists, who have heretofore had little to say about morbid conditions of the Fallopian tubes encountered by them, will be moved to throw light upon the matter. Already a verbal statement has reached us from one of our best-known necroscopists, to the effect that in his post-mortem examinations it has not been uncommon for him to find distension of the tubes. If the records kept by these investigators can be pressed into the service on a large scale, they will doubtless aid materially in settling the question, in a general way, as to how large a proportion of cases of distended Fallopian tubes will probably be found complicated with other lesions that may frustrate a precise diagnosis. No doubt that proportion will be considerable; but, if it does not preponderate overwhelmingly, we may look to see distension of the tubes diagnosed with certainty in a far greater number of instances than hitherto. In cases that are so complicated, of course any operative procedure undertaken must find its justification in mere inference.

With all our recent advances in abdominal surgery, it is still a grave matter to make an incision into the peritoneal cavity without a reasonable approach to certain knowledge of the condition of its contents. In view of this state of things, it would be a great advantage if we could resort, with a fair prospect of success, to other procedures than laparotomy. Possibly it will be found feasible to puncture such collections of fluid through the vaginal wall, establish a free communication with the vagina, and treat the canal of the tube with a view to securing its occlusion throughout. It is conceivable that some of the pelvic collections of fluid that were treated by puncture in the early years of modern gynecology—some-what blindly, it is true, but in many instances effectually—were really examples of distended Fallopian tubes.

From an etiological point of view, it would be interesting to trace what connection there is, if any, between these affections of the tube and the latent gonorrhœa of Noeggerath—a hypothetical condition that met with scant favor when first broached, but which is now admitted as plausible, if not demonstrable, by several observers of good repute.

THE NEW PHARMACOPEIA.

II.

The nomenclature made use of in the work seems to call for some remark, and it may be worth the reader's while to take note of the latinity displayed in it. As to the latter, we have little to say about it, and shall take up its consideration first, in order that we may soon have done with it. Concerning really classical words, the latinity of the pharmacopœia has been ably defended by Dr. Rice, in the columns of one of our contemporaries, in so far at least as certain epistolary criticisms have dealt

with it. There are some of its features, however, that we have not seen mentioned, and a few of these we will allude to now, not so much in the way of criticism as to call attention to them.

The chemical element carbon is endowed with a name of which the genitive is *carbonei*. We do not remember to have met with this word before. Certainly it is not classical, and we can scarcely concede the necessity of coining a word for carbon simply that it might differ from the Latin for charcoal, for the expressions *carbo animalis* and *carbo ligni*, both of which figure in the pharmacopœia, are distinctive enough to do away with any possible confusion. Arsenicum is superseded by arsenium, a word for which there is good classical authority, and one that corresponds with the names now generally applied to many others of the metals. This change, then, seems a good one. The committee seem to have seen some subtle difference in meaning between the terms *crude* and *commercial*, as applied to drugs, for we find *acidum carbolicum crudum* and *chloroformum venale*.

In regard to the foregoing, questions of classical usage properly come up, and changes may legitimately be made in the mere striving after correctness. When it comes to changing made-up Latin words, however, we think that no other consideration than that of practical utility should be regarded. What good purpose is served, for instance, by the declaration that the Latin names of salts in *-ae* and *-is* are masculine? Amyl and diachylon are made indeclinable; hæmatoxyton, however, has the genitive hæmatoxyli. Pulvis opii, apparently by a mere freak, becomes opii pulvis. "Petroleum ointment," commonly called vaseline, receives the name of petrolatum, a word that seems to us ill-constructed, although we are unable to suggest a better one. We think, too, that guarana might better have been called paulinia. It strikes us that the prune might as well have been distinguished from the prunus virginiana by calling it prunus domestica as prunum, the name under which it now figures. We can see but one excuse for such words as bromum, chlorum, and iodum—to distinguish the elements they stand for from the metals; but that can scarcely have been the reason for the change, else why do we find manganum for manganese? There is one change, however, that we heartily approve of—that of distinguishing between the alkaloids and the so-called neutral principles by making their names differ in termination, a rule long ago adopted by the chemists: for instance, the names of alkaloids end in *-ine*, and those of neutral principles in *-in* (e. g., morphine [Latin, morphina], glycerin [Latin, glycerinum]). This has the great practical advantage that it enables the reader to distinguish as to which of the two classes any given principle belongs to without spending the time to look up its chemistry. We find, however, that chinoidin is defined as "a mixture of alkaloids," notwithstanding its neuter termination.

The rule is followed, with a few exceptions, of denoting vegetable drugs by their botanical genus-name, no species-name being added unless more than one species of the same genus are officinal; why, then, cassia fistula, the only cassia that figures as a heading in the pharmacopœia? We can not approve of the practice of writing species names with initial capitals for the

purpose of denoting that such names have been used in the past as genus-names.

The boracic acid of the past is now to be known as boric acid, a thoroughly commendable change, since the substance is not a derivative of borax, but of boron. Ceratum is judged sufficiently distinctive of "simple cerate," but we find elixir aurantii for the only elixir mentioned (simple elixir). The substance usually termed hydrate of chloral is called simply chloral, although we infer, from the chemical formula given, that it is considered as a hydrate. Cologne-water is rather vaguely styled spiritus odoratus.

All these are minor matters, to be sure, but the pharmacopœia should be, like Cæsar's wife, above suspicion.

THE "GOOD STANDING" OF MEDICAL COLLEGES.

THE Illinois law regulating the practice of medicine vests the State Board of Health with the power to grant licenses to practice to persons who fulfill certain specified requirements, which latter vary according as the applicant is or is not a graduate of a medical college "in good standing." As the law does not define what constitutes the "good standing" referred to, the board has felt the need of making such a definition for its own guidance, and in its Fourth Annual Report, a volume replete with information in regard to the sanitation of the State and the regulation of medical practice within its borders, we find the conclusions arrived at by a special committee appointed to report upon the matter.

The committee find that, to be classed as "in good standing," a medical college must enforce the following conditions of admission to its lecture courses: Credible certificates of good moral standing. A diploma of graduation from a good literary and scientific college or high school, or, in default of such diploma, a thorough examination in mathematics, English composition, and elementary physics, the latter provision not to be insisted upon until after the close of the lecture sessions of 1882-'83. The following branches must be included in its courses of instruction: anatomy, physiology, chemistry, materia medica and therapeutics, the theory and practice of medicine, pathology, surgery, obstetrics and gynecology, hygiene, and medical jurisprudence. Each regular session must be of not less than twenty weeks' duration. Attendance on two such courses, both of which shall not fall within the same year, must be required of candidates for graduation. It must enforce the regular attendance of its students during the entire lecture course, allowing only for absences occasioned by the student's sickness, such absences not to cover more than one fifth of the course. Regular examinations, or "quizzes," must be made by each lecturer, or professor daily, or at least twice a week. There must be final examinations on all the branches taught, to be conducted, when practicable, by other competent examiners than the professors. Each student must be required to have dissected during two courses, to have taken at least two terms of clinical and hospital instruction, and to have spent not less than three full years in professional study before graduation,

including the time of instruction by a preceptor and that devoted to attendance upon lectures, clinics, and hospitals. The college must show that it has a sufficient and competent corps of instructors, together with the necessary facilities for teaching, for dissection, for clinics, etc.

In the foregoing we have adhered to the committee's phraseology in the main, simply condensing it. It will be seen that in some respects it is rather vague. It must be confessed, however, that the inquiry with which the committee found itself at work was a knotty one, and, consequently, that precision was scarcely to be looked for in all the details of its conclusions. The board expresses regret that it is not at liberty to exact a higher standard, but we think that in some matters its requirements are beyond what is actually to be found in many of the colleges that would have a "good standing" conceded to them by the profession at large without any question. Indeed, in the list of institutions approved of by the board we find several which do not require of candidates for graduation all the conditions that the committee enumerate. Nevertheless, it seems to us that the committee have done exceedingly well, in view of the difficulties of the undertaking.

The people of the State of New York have for years persistently and stupidly refused to protect their own interests, their health and their lives, by any regulation of medical practice worthy of the name. Illinois, which was a wilderness within the memory of many who are now living, enforces a law that, while it imposes no grievous burdens, can scarcely fail to elevate the medical profession within its borders, and to guard its people against damage at the hands of gross incompetence. That it may shame our legislators into some approach to adequate action is, perhaps, too much to hope for.

A LESSON IN HOSPITAL CONSTRUCTION.

It would scarcely be supposed that the report of a committee, appointed to devise the plan for a new hospital in Italy, would make very entertaining reading for Americans; but there is such a report* before us, which is of rather special interest, embracing some features which it would be well for our American sanitarians to consider and to imitate. The committee who had the building of the hospital in charge evidently regarded the health, happiness, and comfort of the patients as the primary objects to be attained. Accordingly, while preserving a plain, inexpensive exterior, they managed to allot an ample proportion of fresh air and sunlight to each patient, and they arranged their room-space so judiciously as to allow of the complete isolation of contagious cases and maniacal patients, the separation of the kitchens and laundries from the ward-buildings, and the employment of special rooms for the application of electricity, the administration of the hydropathic treatment, etc. In all these respects our New York hospitals are certainly as yet far from perfect. Another feature deserving of imitation is the minute attention paid to details apparently trivial, which are, nevertheless, of great importance for the well-being and satisfaction of the patients—such as the attachment to each ward of sitting-rooms for the convalescents, and of rooms for

* "Piana-Bailotta." Progetto premiato al concorso del Nuovo Ospedale di Lugo in Romagna. Pubblicato a cura della commissione cassa-fabbrica. Bologna: Nicola Zanichelli, 1882.

isolating the noisy, and the addition of separate means of egress for the removal of the dead.

The hospital was designed upon the pavilion plan, and the reasons for the adoption of the special form employed, and a brief comparison of this and the other forms which are in use, are succinctly stated. For this, as well as for many other points of interest, we must refer to the book itself, which we can cheerfully recommend to all projectors of new hospitals, and others concerned in public hygiene, as a useful contribution to sanitary science.

TRICHINOSIS AND THE PRODUCE EXCHANGE.

THE New York Produce Exchange, acting, as we understand, on the strength of a report presented to it by a committee of its members appointed to investigate the question of whether grounds there may have been for the dispute into which American pork has fallen in several European countries, maintains that the authorities of those countries have fallen into error from having misinterpreted a circular issued by certain New York pork-packers for the purpose of gaining for themselves whatever advantage might accrue from a criticism of the methods of packing employed in Chicago. The circular, it is said, maintained that the Chicago packers resorted to objectionable methods of packing their pork, and the Exchange now declares that the document must have been construed abroad as a condemnation of American pork in general. The salacious facts cited by the committee go far to show, if any proof were needed, that there has been some misapprehension about the matter in Europe, but we think the stand taken by the Exchange is not materially supported by the declaration that trichinosis has never been due to eating pork that had been cooked.

THE MEDICAL RECORD.

THIS sterling journal enters upon the year 1883 with its pages enlarged, its paper of better quality, and its typography strikingly improved, having, in short, a most handsome appearance. The valuable matter that its readers have been accustomed to find in it is now worthily presented, and it gives ample evidence that its rehabilitation is none too fine for its substance. Dr. Shrady's long experience as its editor is a sufficient guarantee that the "Record" will continue in the future, as in the past, to supply its readers with a faithful and creditable reflection of contemporary medicine.

Proceedings of Societies.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

A REGULAR meeting was held November 23, 1882. Dr. JAMES TYSON, President, in the chair.

GREAT HYPERTROPHY OF THE HEART, DUE TO SEVERE VASCULAR LESIONS.—Presented by Dr. M. O'HARA, J. B., a male, aged thirty years, laborer, contracted syphilis when eighteen years of age. Health good until within the past three years, when he began to suffer from pain in the left breast, palpitation of the heart, and slight dyspnea after violent exertion. Gradually becoming worse, and unable to work, he was admitted into St. Mary's Hospital in June, 1882. He then complained of a pain over the upper part of the sternum, and in the left arm and shoulder. He lost considerably in weight, his appetite was poor, and albumin was present in small proportion in his urine, although casts were absent. He had marked dyspnea on ad-

mission, which increased rapidly until sleep could only be obtained in the upright position. There was no evidence of pulmonary trouble. While the patient lay on his right side, the brachial arteries became prominent at each impulse of the heart; the position of the carotids was fixed and prominent; the temporals were tortuous and pulsed visibly; no retinal arterial pulsation was seen. Retinal venous pulse was marked, but no visible venous pulsation was detected elsewhere. The left præcordial region was specially prominent. The apex beat was most distinct in the left axilla, and somewhat above the vertical line running midway between the left nipple and the anterior border of the left axilla. The heart's impulse was usually forcible and diffused, but at times it became weakened and wavy. In the second left intercostal space a systolic impulse was observed. The pulse varied from eighty to one hundred and twenty a minute, struck the finger with considerable force, but at once lost most of its volume. All these phenomena were exaggerated by raising the hands above the head. The radial pulses were unequal, but the brachial arteries presented no differences. No hepatic pulsation was felt. The cardiac area of complete dullness was of nearly twice its normal size, the increase being downward and to the left. Over the second right costo-sternal articulation the closure of the aortic valves was distinctly heard, and with this a slight diastolic murmur. A systolic murmur was also heard over the same spot. The systolic murmur was nearly lost in the carotid and subclavian arteries, but the diastolic one remained distinct. On a line with the second costal cartilage, over the sternum and to the left of this bone, the diastolic and systolic basic murmurs were most intense. Over the cartilage of the left fourth rib the murmurs heard at the base of the heart were less distinct, or were obscured by the development of other murmurs. In this situation a short, sharp presystolic murmur, apparently prolonged into a systolic one, was detected. At the apex, and just above it, the systolic murmur became intensified, its blowing character aiding in differentiating it from the short, harsh murmur which immediately preceded it. From the fourth to the seventh rib, and from the sternum to a point about five or six inches to the left, a diastolic murmur of considerable intensity was heard. The character of the diastolic murmur over this area was different from that presented by the second-sound murmur at the base of the heart, and its intensity was much greater. Posteriorly, at the lower angle of the left scapula, a blowing systolic murmur, entirely deprived of its harsh presystolic complication, was heard. Dr. Eskridge thought the physical signs justified him in venturing the diagnosis of constriction and regurgitation at the mitral orifice: a rare form of aortic regurgitation produced by the inability of one of the aortic semi-lunar valves to close while the others acted properly; great hypertrophic dilatation of the left ventricle, and to a less extent of the left auricle, and minimal dilatation of one of the great vessels, probably of the pulmonary artery near its origin from the heart. The patient rapidly sank. (Edema of the lower portion of the trunk and lower extremities, with hydrops pericardii et pleura et peritonei) developed. He died, exhausted, in August, nearly two months after admission to the hospital.

SECTION ON ANATOMY.—Report of the dissection of the pia mater. The brain substance and the ganglia nearly normal in appearance. Thorax: The pericardium was nearly filled with serum. The only abnormality observed was a few patches of recent lymph at the left anterior upper portion of the sac. The heart was dilated, and the coronary vessels being chiefly due to eccentric hypertrophy of the left auricle and ventricle. The right ventricle was dilated, with slightly thickened walls. The aortic valves were insufficient and thickened. The pulmonary orifice was normal in shape, but the valves could

upon themselves on the aortic side of the orifice. The stenosis was slight. The mitral orifice was button-hole-shaped, and the valves failed to close on account of calcareous deposits in their tissues, this degeneration also involving the inner surface of the left side of the auricle contiguous to the valves. The auricular surface of the valves was fairly smooth, but in the ventricle just beyond the valves, and attached to them, hung a bony substance about one eighth of an inch in diameter. The left auricular appendix was much hypertrophied. The valves at the tricuspid and pulmonary orifices were normal. The pulmonary artery was considerably dilated. The pleural cavities contained several ounces of serum. There were old adhesions at the apex of the right lung posteriorly, and at the same part of the left lung anteriorly. Several patches of recent lymph were also found at the lower part of the left pleural cavity. Abdomen: The peritoneal cavity contained considerable serum, and its veins were engorged. The liver was enlarged with distended veins. The kidneys were highly congested. The spleen was of double its normal size, and softened.

ABSCESS OF THE LIVER FOLLOWING ARRESTED MENSTRUAL DISCHARGE, FROM EXPOSURE TO COLD; PYÆMIC ABSCESSSES OF THE LUNGS AND SPLEEN; PERFORATION OF THE BOWEL; SEVERE HEART COMPLICATIONS; DEATH DURING THE SEVENTH WEEK.—Presented by Dr. J. T. ESKRIDGE. M. D., aged twenty-eight years, was a factory girl, whose father and two sisters had died from heart disease. She had had two attacks of inflammatory rheumatism, but had never complained of heart trouble. Her fatal illness began at night, by arrested menstrual flow, and severe cramping abdominal pains, coming on after exposure to cold during the previous afternoon. Fever and pain in the right lower side of the abdomen continued for three days, when she was able to work again for about a week. Jaundice began early, was well marked during the first three weeks, was slight afterward, but lasted until her death. Her symptoms three weeks after the beginning of the attack, when admitted into St. Mary's Hospital, in Dr. Hickman's wards, were, great prostration, emaciation, loss of appetite, pain in the right inguinal and lumbar regions, and irregularly recurring chilly sensations. Two weeks later, when first seen by Dr. Eskridge, the liver dullness extended nearly to the anterior superior process of the ilium, and the normal tympanitic note of the right inguinal region of the abdomen was replaced by one bordering on dullness. The tenderness was so great that neither fluctuation nor a tumor could be detected, if such existed. Great tympany soon developed, and obscured the physical signs. A pyæmic condition, from which the patient perished in about two weeks, set in, attended by chills, fever, sweating, low temperature, and diarrhoea. A few days before death she passed considerable pus by the bowels. The surface temperature, taken over the chest and abdomen, showed the latter to be about two degrees warmer than the former, but all parts of the abdomen were of nearly the same temperature. Stenosis of the aortic and mitral orifices, with insufficiency of the valves of the latter, and a dilated hypertrophy of the left auricle and ventricle, were recognized during life. The post-mortem examination revealed the lesions of the heart diagnosed, and demonstrated the possibility of visible left auricular pulsation. The liver weighed eighty ounces (the right lobe being alone enlarged), and contained a large abscess, surrounded by several smaller ones with which it was connected. The cæcum and its appendix were surrounded by about six ounces of pus, the latter being circumscribed by adhesions. Two openings were found in the black and gangrenous cæcum—one where its appendix had sloughed off, the other due to perforation of the bowel by the pus. The portion of the liver external to the hepatic abscess was firmly adherent to the abdominal wall, and from this point (about two inches above

the crest of the ilium) the pus had borrowed its way and formed a sinus leading to the right inguinal region under Ponpart's ligament. A direct communication between the liver abscess and the accumulation of pus surrounding the cæcum was seen.

Dr. Eskridge thought that the demonstration of the possibility of visible left auricular pulsation in the second left intercostal space, and of the occurrence of a functional murmur in the pulmonary artery without dilatation of that vessel, was worthy of notice at present, as Dr. Broadbent had so recently advocated views almost diametrically opposite. Dr. Eskridge considered mitral stenosis of not infrequent occurrence, and said that with care the mitral presystolic murmur was not usually difficult to detect. The four physicians, including himself, present at the autopsy, then thought that the hepatic abscess was secondary to the inflammation and suppuration around the appendix and cæcum, but he, after carefully analyzing the clinical evidence and pathological lesions in favor of each condition, was satisfied that the case began as one of primary abscess of the liver, following exposure to cold while the patient was menstruating.

The discussion on both the preceding specimens, which presented somewhat similar heart lesions, was now opened by Dr. J. C. WILSON, who said that there was one point of special clinical interest in Dr. Eskridge's case, viz., the chronology of the lesions. He thought that the extensive multiple abscesses of the liver and lungs were secondary to the abscess around the caput coli. In some cases the determination of the primary source of the emboli was difficult, but in this case it was perfectly clear.

Dr. BRUN said that he would like to go on record among those who had observed auricular pulsation in cases of mitral obstruction in which the stenosis was extreme.

Dr. NANCREE remarked that in his experience flexion of the thigh on the abdomen was an almost invariably early symptom in cases of perityphlitis, from which he would infer that, as this thigh flexion did not occur in Dr. Eskridge's case until within ten days of the fatal termination of the case, the circumcæcal abscess was secondary to that in the liver.

Dr. TYSON said that he had been much impressed with the marked increase of the surface temperature in the neighborhood of the abdominal abscesses as compared with the general body temperature. As to the chronology of the various affections, he was inclined to believe that Dr. Wilson was correct.

Dr. ESKRIDGE said, in reply to Dr. Wilson, that he could appreciate how the perityphlitis might be mistaken for the primary trouble, and the hepatic suppuration for the secondary; such a mistake (for he felt certain that the abscess of the liver was the primary affection) was made by all, including himself, who were present at the post-mortem examination. The pathological and clinical facts in favor of primary hepatic abscess were given at some length in his remarks in connection with the presentation of the specimens. In brief, the clinical features were as follows: Deep and early jaundice following exposure to cold; pain in the right side of the abdomen, attended by fever and gastric irritability of a few days' duration; an intermission of a week, during which she was able to work, followed, after which, gradually increasing weakness, with dull abdominal pain, attended by loss of flesh and appetite, confined her to bed; ten days before death, the development of intense tympany, associated with flexion of the right thigh upon the abdomen. The hepatic suppuration was confined to the right side of the right lobe, all the smaller abscesses directly communicating with the large one, and the left lobe of the liver being apparently healthy.

TONGUE AND LARYNX FROM A CASE OF ELEPHANTIASIS GRÆCORUM.—Presented by Dr. A. C. W. BEECHER. The case which furnished the specimens was reported in the "Photo-

graphic Review of Medicine and Surgery," No. 6, vol. i, August, 1871. Mr. —, aged twenty-six years, born in Cuba of Spanish parents, married. His father was living when the patient died in 1872; the mother died when he was an infant. He was wet-nursed by a colored house-servant, who was unmarried, but had had several children by different individuals. She was healthy so far as known, with the exception of sores upon her feet. He had none of the diseases of early life except measles and mumps. His health was good up to fifteen years of age, when superficial yellowish-pink spots appeared upon his body, accompanied by neither pain nor itching. They remained about one year, and disappeared during a voyage to Spain. While there he was attacked with neuralgia of the little fingers, extending along the course of the ulnar nerve to the elbow, which was relieved, and he returned to the West Indies. Six months after his return he experienced a second attack, which lasted for one month. In 1862 he came to this country to study, and after one year became the subject of repeated catarrhs, chiefly affecting the throat. Itching of both forearms and legs soon after developed. In 1866 œdema of the hands and feet, which did not extend beyond the wrist or ankle, set in, producing a sensation of stiffness of the fingers and toes. Blisters then suddenly appeared in varying size upon the dorsum of the hands and fingers, extending over the whole length of the latter. At times a sharp pain in the hands and fingers, arousing him from sleep, would herald one of these bullous attacks. The bullæ contained a whitish opaque fluid, and when burst were succeeded by dark-brown scabs, transversely cracked and fissured over the joints. Under these crusts were excavated ulcers. The finger tips and the ends of the toes presented similar ulcers, over which the nails grew, and these latter, being brittle, broke off when long. Next, frequent hæmorrhages from the nose, coming on while laughing or in mental or physical excitement, were observed. The nose became tender, was much swollen, and discharged moderately offensive pus, and the bridge of the nose began to sink, gradually assuming its present appearance. (A photograph was here shown.) A year after the hands were attacked, the face became similarly affected, the ulcers on healing leaving distinct cicatrices. The eruption never entirely ceased, new bullæ and ulcers forming while others healed. There was marked emaciation. The hair, which was everywhere scanty, was absent in many parts of the body, and the skin was of a dusky hue. The muscles of the arms were much wasted, and the skin presented small white cicatrices. Over both patellæ and olecranon processes, large, hard, firm, reddish nodules were seen. The hands were much deformed, with wasted, contracted fingers, having numerous small hard tubercles scattered beneath the skin of the dorsal surface of the hands. Numerous ulcers, mostly covered with irregular black scabs, covered the back of the fingers. A markedly varicose condition of the veins near the wrist was observed. The hair of the head was normal in quantity, but was hard and harsh, while there was total loss of eyelashes and eyebrows, and the beard was scanty. There was a large hard tubercle over one frontal boss, near which was an old ulcer. The nose was much sunken, there was an ulcer over the right zygoma, covered by a black rupial-like scab, the face was marked with scars, and the ears were likewise deformed with traces of numerous cicatrices. Many of the teeth were decayed and broken off close to the gums. The tongue was much thickened with greatly enlarged papillæ. The velum palati was almost gone from ulceration, and yellowish-white tubercles existed in the pillars of the fauces. The larynx was much contracted by thickening of its mucous membrane. The epiglottis was of about twice its normal thickness, and had several well-marked tubercles upon it. The voice was much impaired, weak,

and had a peculiar husky sound. There were deep sloughing ulcers over each tendo Achillis. Tactile sense was very much impaired, as in the dorsum of the hands, where the sense of touch was almost absent, and what was recognized was referred to some point in the neighborhood of the point of contact. The sense of pain was almost entirely absent in the hands and forearms, becoming more marked as the body was approached; a pin passed through the pulp of the middle finger gave absolutely no pain. The difference between very hot water and that of an ordinary temperature was readily perceived; moreover, there was general increased cutaneous sensibility to temperature changes. Taste and smell were somewhat impaired. Very slight anæsthesia of the trunk existed. Sight was good, although prolonged use of the eyes was painful. The general health of the patient was fair. There seemed to be no trace of venereal disease. Sexual power was absent. Frequent neuralgic pains of the legs and arms were complained of. The atrophy of the hands, feet, fingers, and toes was appreciable from month to month. The cornea next became ulcerated, the conjunctival surfaces became adherent, and almost total blindness ensued. Swallowing was almost impossible toward the last, owing to the pain produced by the throat ulcers, and because, from imperfect closure of the rima glottidis, fragments of food entered the larynx, producing violent and exhaustive coughing. Respiration was also so much impeded that he died October 29, 1872, partly from dyspnoea, partly from starvation. Up to death he suffered intensely.

Autopsy.—Rigor mortis well marked. Great emaciation of the entire body noted. The surface of the tongue was fissured, the papillæ being enlarged, with the remains of tubercles well marked toward its base. The epiglottis was curved on its long diameter, thickened and stiff, with its upper margin eroded by a large ulcer. A deep ulcer was situated in the mucous membrane near the apex of the left greater cornu of the hyoid bone. Narrowing from thickening of tissues involved the trachea at its upper part, and produced such stenosis of the chink of the glottis that an ordinary quill could not be passed between the vocal cords. Upon section of both ulnar nerves near the elbow, extensive degeneration was detected. This case was examined both by Dr. Duhring and Dr. R. M. Bertholet—the latter making a laryngoscopic examination—who both considered it to be of the mixed variety, viz., tubercular and anæsthetic leprosy. The case was interesting both from its variety and the possibility of other cases being brought here from California and New Brunswick, in both of which places it was not uncommon. "Again, its resemblance to syphilis at first led me into error, although," said Dr. Beecher, "I recognized something strange about the disease. The late Dr. Maury saw the case with me, and had no doubt of its syphilitic nature until Dr. Duhring's examination convinced him that it was really leprosy. Erasmus Wilson says: 'The resemblance to secondary syphilis is so striking that an error is certain excepting on the part of those who have had an opportunity of seeing and observing leprosy.'"

Dr. Wilson asked whether the family history had been investigated. Dr. Beecher replied that he had carefully questioned all concerned, but had ascertained nothing special, except that, when such cases occurred in wealthy families, the fact was always hushed up. Dr. Wilson said that in this connection he would call the attention of the members to a very able article in the last issue of "The American Journal of the Medical Sciences," where the writer took the view that leprosy was contagious, maintaining that it should be investigated where it was of rare and recent occurrence. Dr. Wilson also referred to its occurrence among recent immigrants in certain of our north-western States.

Dr. CARL SEILER said that Dr. Beecher had asked him to examine the specimens of the larynx and tongue of the case of elephantiasis. The dorsum of the tongue was deeply furred, and the papillæ appeared enlarged. The epiglottis was thickened, very stiff, and rolled on its long axis like a dry leaf. On its upper free margin was a crescentic ulcer with raised edges, and numerous smaller roundish ulcers were scattered over the laryngeal surface of the epiglottis. Extensive ulceration of both ventricular bands and vocal cords existed, so that the opening of the ventricles was almost entirely occluded. The ulcers were symmetrical, and most marked toward the anterior insertion of the vocal cords. About one fourth of an inch below the cords was a cicatricial band projecting from the sides of the subglottic cavity, and leaving an elliptical opening, through which a crow-quill could hardly be passed. Below this obstruction the mucous membrane of the subglottic cavity was studded with small, round ulcers, while the trachea seemed healthy. No further lesions could be detected by the naked eye, although, doubtless, such had existed, but had been obscured owing to long preservation in alcohol. Dr. Seiler regretted the absence of the records of the laryngoscopic examinations made before the patient's death, still the lesions seen in the specimen would explain the symptoms of dyspnea, aphonia, and dysphagia, and it was astonishing how the patient could have respired at all through the narrow opening left by the cicatricial tissue below the glottis. The chief interest, however, centered in the great similarity of the lesions in this unique case with those found in syphilis and lupus of the larynx. He had seen ulcerations in syphilitic laryngitis almost identical in shape and location with those seen in the specimen, and he remembered having seen two or three specimens of lupus of the larynx when in Vienna which bore a strong resemblance to syphilis. Lupus and leprosy of the larynx could not be diagnosed from one another by laryngoscopic examination alone, but other signs and symptoms outside of the larynx had to aid in the diagnosis. Thus, in a syphilitic laryngitis, there were always sharply defined bands of a deep-red color on the free margin of the velum palati. In lupus, affections of the skin of some parts of the body always preceded, coexisted with, or shortly followed the manifestations of the disease in the larynx, while in leprosy the larynx was usually attacked later in the disease, when other portions of the body clearly showed marks of the pest.

Dr. LITTLE remarked that, having conversed with Dr. F. N. Enders, who had seen a great many cases of leprosy in the Sandwich Islands, he had been interested to note that the eyelids were affected in the early stages, ectropion resulting, and the conjunctiva and cornea, or even the whole eyeball, becoming involved. The affection of the eyelids was sometimes the first symptom, or occurred during the first or second year of the disease. The lids were involved in the case described, and the eyeballs subsequently.

DILATATION AND ATHEROMA OF THE PULMONARY ARTERY, WITH AN OPENING THROUGH THE INTERVENTRICULAR SEPTUM.
—Presented by Dr. BRUEN.

Examination of the Heart, Left Side.—Slight ventricular hypertrophy; mitral valves somewhat thickened at the margins, with roughening of their auricular aspects; valves competent. The left auricle was normal, as were also the aorta and the aortic valves. Examination of the right heart was of more interest. Two of the semi-lunar leaflets at the mouth of the pulmonary artery were nearly destroyed by atheromatous changes. The third segment was much thickened, and projected as a leaf-like fold, roughening the mouth of the pulmonary artery. This vessel was dilated to nearly twice its normal size, forming really an aneurismal dilatation. The vessel's walls were covered with

a fringe of vegetations of inflammatory origin or due to atheromatous changes. The right auricle was very small and imperfectly developed, the bulk of its cavity being formed by the auricular appendix. The tricuspid valves were much thickened, but were probably competent. Between the two ventricles was an orifice large enough to admit the forefinger. It was directly beneath one of the tricuspid leaflets, and was lined with endocardium, and must have allowed a free interchange between the blood of the two ventricles. The walls of the right ventricle were thinned and its cavity was somewhat dilated. Dr. Bruen said that this case was interesting because: 1. Perforation of the ventricular septum was often congenital, and dependent on obstruction of the orifice of the pulmonary artery, the perforation being due to the pressure of blood within the replete right ventricle. This pressure caused an arrest in the development of the ventricular septum. The pathology of the present case probably was as given above, but there was no pulmonary artery obstruction. A similar case was recorded in the "Medico-Chirurg. Trans.," vol. xv, by Fletcher. 2. There was no cyanosis. Cyanosis was usually dependent on a deficiency of cardiac evolution, or else on retarded evolution of the pulmonary artery or aorta. As a consequence, there was deficient cardiac power to carry on the circulation; or the pulmonary artery or the aorta was narrower than normal, so that in any of these conditions a venous repletion resulted, and cyanosis, i. e., mixture of the venous and arterial blood, was then not the usual cause of cyanosis, although it might be a factor. Walsh said: "Grant that perforation of the ventricular septum coexists with constriction of the pulmonary orifice, and cyanosis seems to become a certainty." In our case there was an example of incomplete development of the ventricular septum, and deficient development of the right auricle without cyanosis. 3. Pulmonary-artery disease was consistent with a fair amount of general health, and compensation by the right heart might occur, just as in cases of aortic disease. 4. Descriptions of pulmonary-artery disease called attention to bronchitis, pneumonia, hydrothorax, as sequential states. In our case no such complications were present until just before death, when she finally succumbed to congestion of the lungs added to the cardiac state. 5. The aneurism of the pulmonary artery formed a pulsating tumor on the left side of the sternum, between the second and fourth ribs, extending outward from the border of the sternum and including an area covered by a trade dollar. 6. Over the tumor a post-diastolic and a presystolic bruit-like murmur could be heard at a point between the second and fourth ribs, while close to their junction with the sternum a hoarse systolic murmur could be heard. The bruit was localized; the heart systolic murmur was carried out into the entire arterial system.

Dr. Bruen then detailed at length the differential diagnosis of these murmurs. During life, dilatation of the pulmonary artery with mitral obstruction had been the diagnosis. The patient was a woman aged twenty-four years, a syphilitic, and was under observation from November, 1878, to July, 1882.

Dr. ESKRIDGE had no difficulty in differentiating a presystolic from a diastolic murmur. He thought the leathery thickening of the mitral valves in the specimen presented by Dr. Bruen was sufficient to give rise to a mitral presystolic murmur. If we adopted the theory of Dr. Austin Flint, Sr., that a mitral presystolic murmur might occur in aortic regurgitation when the mitral valves were perfectly healthy, it seemed to him that there was no difficulty in accounting for the presystolic murmur from the regurgitant blood from the pulmonary artery into the communicating right and left ventricles of this case, especially as thickening, loss of elasticity, and some rigidity of the mitral valves existed. The chronometry of the pulsations that occurred

in the left second intercostal space, he thought, could have been obtained by adopting Sanson's modification of Balfour's method of comparing the time of the occurrence of precordial pulsations.

Dr. SHAKESPEARE said that he had been struck with one point of great interest in connection with inflammation of the lining coat of the pulmonary artery, as evinced by the vegetations. These growths were very rarely found in the venous current. He had certainly never seen any other specimens, although he did not doubt that some had been seen or reported by other observers. Arterial blood seemed a requisite for the evolution of such diseased action. Evidently the site of the perforation being just below the aortic and pulmonary valves brought about just this necessary prerequisite, viz., admixture of arterial blood with the venous.

Dr. WILSON called attention to the evident relation between the incomplete ventricular septum and the condition of the pulmonary artery, which was greatly dilated and atheromatous, and presented the appearances often met with in the aorta, very rarely in this vessel. The wall of the right heart was relatively thickened. This fact, together with the position of the opening in the inter-ventricular wall, which favored the flow of the blood from the left ventricle toward the pulmonary artery, rendered it probable, almost certain, that the more forcible contraction of the left heart had constantly forced a portion of its arterial blood into the right heart, thus increasing the current entering the pulmonary artery, and occasioning, first, hypertrophy of the right ventricle, and, second, a subacute inflammatory process in the pulmonary artery itself, in consequence of the increased volume and force of the blood-current. Dr. Shakespeare's observation that such growths as were here seen required for their existence arterial blood, was in accordance with this view.

SARCOMA OF THE PROSTATE GLAND.—Presented by Dr. W. H. HUGHES. The specimen was taken from a patient in the University Hospital, under the care of Dr. H. R. Wharton:

W. L., aged thirty-five years, admitted to the University Hospital suffering from retention of urine. Before his admission, numerous unsuccessful attempts had been made to empty the bladder by means of a catheter. On admission, the patient complained of much pain in the hypogastric region, which was the seat of a smooth rounded swelling reaching almost to the umbilicus. He stated that some years previously he had gonorrhea, which had been followed by a troublesome stricture, which had been perfectly relieved by the passage of bougies. For more than a year previous to his admission he had suffered, at irregular intervals, from difficulty in urination. The urine had never been bloody, but its passage had often been attended by great pain. It was found impossible, on account of numerous false passages, to introduce a catheter into the bladder. On introducing a finger into the rectum, the prostate was felt smooth, rounded, and immensely enlarged. The patient was put to bed, ordered suppositories of belladonna and opium, and to have a warm poultice applied to the abdomen. This treatment relieved him almost immediately, and urination became freer. For a few days he did well, but the difficulty in urination soon began to increase, and by the fifth day after his admission the symptoms had become so urgent that it was deemed advisable to repeat the attempt to pass a catheter. This attempt was as futile as the first. Then aspiration of the bladder through the abdominal walls was attempted, but only a small quantity of blood was obtained. In introducing the cannula, it gave the sensation of passing into a solid body, and careful palpation revealed the fact that there really was a solid body apparently occupying the whole bladder. It was now decided to open the urethra at the base of the bladder through the perineum, and the operation known as Cock's was selected. The

operation was followed by the escape of a small amount of urine. After this the patient did well, with the exception of an attack of dysentery, until the ninth day after the operation, when peritonitis suddenly developed. He died on the following day.

Autopsy (two hours after death).—Upon opening the abdomen, a thick, yellowish-red, purulent liquid, having a urinous odor, was found bathing the intestines, the coils of which were everywhere bound together by recent adhesions. The omentum was in places firmly adherent to the intestines, and contained numerous irregular nodulated masses, varying in size from that of a pea to that of a hen's egg. These masses, on section, presented a whitish-yellow color. In the lower part of the abdominal cavity was a large, irregularly shaped tumor, firmly adherent to the small intestines, colon, omentum, and walls of the pelvis. On careful dissection, the tumor was found to originate in the prostate gland. On section, it presented in parts the characteristics of scirrhus; in others, those of encephaloid; in other places there were large loculi, with reddened, irregular, friable walls, filled with a liquid similar to that found in the abdominal cavity, though no connection between these loculi and the abdominal cavity could be found. No trace of normal prostate gland nor seminal vesicles could be discovered. The bladder, containing a few ounces of urine, was found in front of the upper portion of the growth, its upper boundary almost on a line with the umbilicus. Its anterior wall was apparently perfectly normal; its posterior wall, resting on the tumor, was thickened, raised, red, and velvety. The ureters were normal, and opened in the usual position. The urethra, as far as could be seen, ran along the anterior surface of the tumor and was not involved by it. The weight of the growth was five pounds two ounces. The kidneys, stomach, lungs, and intestines were normal. The peritonæum and capsules of the liver and spleen contained several secondary growths. The brain was not examined. Microscopic examination showed the growth to be a typical small-round-celled sarcoma. The secondary deposits were similar in structure to the primary growth. The submucous and muscular tissues of the bladder-walls were somewhat infiltrated. The growths in the capsules of the liver and spleen had commenced to penetrate those organs.

MELANOTIC SARCOMA OF THE ORBIT, WITH METASTASES TO THE LIVER, ETC.—Presented by Dr. SHAKESPEARE.—The patient was an elderly woman who had been operated upon by Dr. Heyl at the Episcopal Hospital some six months before death, the whole contents of the orbit having been then thoroughly removed. Recurrence took place, the cavity being filled with a black fungating mass; the left nostril gave vent to a blackish discharge, and the various internal organs became involved, notably the liver. Death took place from exhaustion. Most of the metastases were entirely melanotic, but some in the liver showed at their periphery a distinct whitish zone. Dr. Shakespeare remarked upon the singular fact that orbital growths were usually melanotic, although they might not spring from the choroid coat of the eye, as in this case, where all pigmented structures had been removed months ago.

C. B. NATHAN, M. D.

Remover

SULPHOCARBONATE OF SODIUM FOR VOMITING.—Mr. Philip Mail (*C. Brit. Med. Jour.*, 7 Dec. 10, 1882) refers to the well-known efficacy of this drug in cases of flatulency, vomiting, and also that he has found it occasionally as a remedy for vomiting, particularly the vomiting of pregnancy, in doses of scruple given in half an ounce of water. Sometimes, but less often, it induces vomiting than it produces arrest of the uterus, and in one case it seemed to alterate the uterus.

Reports on the Progress of Medicine.

QUARTERLY REPORT ON PSYCHOLOGICAL MEDICINE.

No. VIII.

By NORTON FOLSOM, M. D.,
BOSTON.

[In connection with the first three articles here summarized, the reporter would suggest that the impossibility of a perfectly satisfactory classification of mental diseases—that is, of one which admits of all cases being so grouped as to satisfy all authorities—is sufficiently demonstrated by the numerous attempts which have been made, and which continue to be made, in the direction of elaboration and minute discrimination, while the most simple systems are still the most generally acceptable.

For statistical purposes, or the comparison of general facts and results, a simple and arbitrary system will always be the most desirable, or, at any rate, until pathological investigation has gone deep enough to warrant classification on anatomical grounds—probably a very distant time. At present the classification in most common use in framing the reports of institutions for the insane is essentially that proposed at the beginning of the present century by Esquirol, comprising the groups of melancholia, mania, monomania, dementia, and imbecility or idiocy. Epilepsy and general paralysis are complications rather than distinct classes. The terms acute and chronic may be justly applied to many cases in several of these classes, but this does not render subdivision necessary, for the same individual who enters an asylum with acute mania, for instance, will, if recovery does not occur, be said to have chronic mania after a period of time varying with the judgment of different observers. Indeed, a classification can apply rigidly to a series of cases only at some one stated time, for change or alternation in the form of disease is very frequent.

For purposes of study in detail, however, much more minute classifications are used. These systems are descriptive rather than definitive, and authorities vary so much in the practical application of fine distinctions that their introduction into statistics is rather to be deprecated. Subdivision and pseudo-scientific nomenclature have been carried to an absurd extent; and it has seemed at times as if new monomanias were invented solely to bring notoriety to the inventor.

Where, however, a group of cases has a sufficiently distinctive form to meet with general recognition instead of repudiation, and especially if any practical points in the prognosis or treatment can be shown to exist in common among them, the study of such a group becomes profitable, and the interest of its natural history is enhanced. It is very rare to find the boundaries absolute of such a group, however, and the effort to establish any characteristic pathological condition generally fails completely. A general resemblance in clinical history, or the possession of one or two salient points in common, is frequently held as sufficient ground for setting it up in business as "an independent morbid entity," with a high-sounding name compounded with more or less violence from the resurrected remains of dead languages. No harm is done if the essentially artificial character of the new disease is borne in mind; but, as in the instances of "kleptomania" and "dipsomania," very vicious nonsense may be uttered as the result of confounding the facts in the case.]

FOLIE À DOUBLE FORME.—Dr. Achille Foville ("Brain," Oct., 1882), in an amplification of his article in the "Nouveau dictionnaire de médecine et de chirurgie pratiques," translated

by Dr. A. R. Urquhart, strongly urges the claims for recognition as a separate disease of what was, almost simultaneously, originally described by Drs. Falret and Baillarger, physicians to the Salpêtrière, under the name of "*Folie à double forme*." He somewhat naively precedes his definition of the disease by the following quotation from Griesinger, published before the observations above alluded to: "The transition from melancholia to mania and the alternations of these two forms are very common. It is not rare to see the whole disease consisting of a cycle of these two states, which often alternate very regularly." [The fact is that the whole truth of the matter is here contained in a nutshell.]

The definition of the disease, also called *folie circulaire*, given by Foville, is as follows: "A species of insanity characterized by a prolonged succession of periods of maniacal excitement and of periods of melancholic depression, usually alternating in a regular manner. The duration, intensity, and type of the excitement and depression, and the mode of transition from one to the other, may greatly vary; but their alternate recurrence is constant and pathognomonic. This species of insanity is almost always owing to the development of an hereditary predisposition; and most often it is incurable.

The only element in this definition which is claimed to be absolutely constant is the *alternation*; and yet the tendency to a more or less complete periodicity, the typical development of which is a regular ebb and flow, or *alternation*, is so manifest in nervous disease—in disease in general—and even in healthy vital phenomena, that it seems to be the result of a general law, rather than a distinction peculiar to these cases.

The matter of most practical interest is that, after the regular habit of alternation is once established, it is nearly sure to continue without much change. As it is a confirmed or chronic type of disease, the cause is most frequently found to be of a permanent character, such as heredity or physical injury. It would be very interesting to learn whether, conversely, a large proportion of all the cases of hereditary origin assume the alternating form. It occurs much more frequently in females, and generally before the age of thirty years. The intensity of the disease and the duration of the paroxysms vary extremely in different individuals, but are remarkably constant in repeating themselves in the same person in different alternations. The weight and physical health are thus temporarily affected in different degrees; but, except at the acme of excitement or depression, in cases of severest type, the general health is usually remarkably good, and, as termination in dementia is very rare, the patient is likely to reach a greater age than in other types of disease. The frequency of the paroxysms is variable, but the circle seldom requires more than a year for its completion. In some cases it has been noticed that the depression regularly occurs in winter, and the excitement in summer. The occurrence of apparently lucid intervals is the rule; and in some cases the patient remains for months, and even years, in normal condition. [Such cases as these have given rise to considerable discussion as invalidating the statistics of recovery from insanity. As the patients are recorded as cured every time they are discharged from the asylum, they are said to swell the number unduly, as it would be naturally assumed that the number comprised so many different individuals, and the percentage of recoveries be determined on that basis.]

As has been said, the disease is apt to repeat itself very exactly, and, whatever degree of health is attained to in one interval is attained to in all, through life. In those cases where the normal standard is not quite reached, yet where restraint in an asylum is not continued, there is a special liability to get into trouble with the rest of the world, and some of the medico-legal problems which result are difficult to solve. Vagrancy,

morbid impulses to overt acts, and malicious conduct, are common features in such cases. There are other patients, again, who are able to get along in the world through periods of moderate depression and during lucidity, only requiring hospital care during comparatively short accessions of excitement.

No special anatomical change can be demonstrated as characteristic of these cases. M. Luys has advanced the theory that alternate hyperæmia and anemia are the underlying conditions, but the proof is lacking. Even if these conditions were proved to accompany the alternations of the disease, it would remain uncertain which was cause and which effect.

THE TREATMENT OF PERIODIC INSANITY.—Dr. H. M. Hurd, of the Eastern Michigan Asylum ("Am. Jour. of Insanity," Oct., 1882), in view of the failure of continuous asylum treatment in periodic insanity, advises experimental changes from ward to ward, or discharge from the asylum when remissions will allow, in the hope of its favorable influence. He has witnessed decided benefit from the administration of hyoscyamine, in the dose of one twentieth of a grain, given upon the eve of an outbreak of circular mania. It produced intoxication lasting several hours, followed by deep sleep, from which the patient awoke clear in mind and free from mental disturbance. In this individual the recurrence of the disease was apparently prevented for several months.

Dr. Hurd remarks that there is rarely such an accurate balancing of opposite conditions as the classic descriptions of *folie circulaire* would indicate.

KATATONIA.—Under this name Dr. Kahlbaum, the superintendent of a private asylum at Görnitz, Prussia, avers that a distinct form of insanity should be recognized, the distinguishing characteristic of which is an irregularity, or, as he phrases it, an insanity, of tension, mental and muscular. The first symptom noticed, as in other forms of insanity, is a change in the temper of the individual. It presents, at times, well-marked motions of a rhythmic character, always under the control of the will—thus differing from chorea. Another feature is its cyclical character, maniacal, melancholic, and cataleptoid conditions alternating with more or less imperfect convulsive attacks; there are also pathetic delusions of grandeur, and a tendency to act and talk theatrically. Erotic manifestations frequently occur, and the ideas have a religious tinge. At any stage, remissions or complete recovery may occur. If the case is to end unfavorably, periods of excitement and stupidity recur more and more frequently, and the patient dies with terminal dementia.

Singular as is the picture presented, the evidence is ample that it represents a definite disorder. Dr. Kiernan, whose article ("Alienist and Neurologist," Oct., 1882) is full and conclusive, after giving Dr. Kahlbaum's views, narrates five cases in detail; and, where opportunity is found for post-mortem examination, the appearances are pathognomonic. The disease is said by Kahlbaum to be very rare, but Dr. Kiernan found the disease in about two per cent. of the whole number admitted to the New York City Asylum. It is by no means so fatal a form of disease as would be at first supposed. Dr. Kiernan has seen ten patients recover out of forty-six. This is the more remarkable as the post-mortems show "a healed-up hydrocephalus and a basilar meningitis." Meynert deduces that the disease has always been preceded by a patho-meningeal process, located at the base of the brain and over the fissure of Sylvius. Dr. Kiernan concludes, from his experience with this disease, and with tubercular meningitis in children, that many of the so-called hydrocephaloid cases are really hydrocephalus, and that tubercular meningeal processes are more frequently recovered from than is generally supposed.

The duration of katatonia is from two to five years. The treatment should be tonic, and stimulants are of service. Cocaine is indicated by motor disturbance. The nitrite of amyl has seemed to be of benefit in ten cases, and it has caused a pleasurable feeling in all where it has been given. Faradization of the muscles is also recommended. Moral treatment is of importance, as in all forms of insanity.

LUNATIC ASYLUMS IN GREAT BRITAIN.—Dr. P. M. Wise ("Alienist and Neurologist," Oct., 1882) endeavors to state impartially the chief differences existing between the asylums on either side of the Atlantic in the features favorable to British Asylums. He visited eighteen asylums in Great Britain in 1882, thirteen of which were for the care of paupers.

The differences are: in the uniformity and thoroughness of surveillance; in methods of construction, with a view to grouping patients for sleeping and dining purposes in large associate dormitories and halls; in the removal of patients from the apartments occupied at night to others specially designed for day uses; in an efficient night service; in the development of the industrial system; in the absence of mechanical restraint and the greater degree of personal liberty allowed.

Dr. Wise does not absolutely commit himself to the theory that insanity in Great Britain assumes milder forms than with us, though he states that it would so appear at first sight, or else that the class of insane composing their asylum population is quite different from that to be found in ours. He bears cheerful testimony to the admirable character of the results of the English methods.

CHRONIC MORPHINISM.—Dr. H. Obersteiner ("Brain," Oct. 1882) does not advise trying the "weaning cure" for the morphine habit unless there is good reason to expect a successful issue. He finds that in certain cases the starting-point of the habit lies in some mental disturbance. He concludes with the following propositions:

1. A real and persistent result after the "weaning cure" is very often doubtful, or is not obtained; the cure itself may, under certain conditions, endanger life.
2. In most cases the protracted use of morphine in large doses is followed by psychical alterations of a lasting nature, which may amount to decided insanity.

RESTRAINT AND SECLUSION IN AMERICAN INSTITUTIONS FOR THE INSANE.—Dr. H. M. Bannister and Dr. H. N. Moyer ("Jour. of Nerv. and Ment. Dis.," July, 1882) have received statistical information from twenty fairly representative institutions in this country in regard to restraint and seclusion. They conclude that, as they say was already well known, the average use of such means is high in American institutions, and in some of them excessively so. It is shown, however, that practical non-restraint is possible with our methods of asylum construction and our insane population, and that restraint has less value for some of the more important ends for which it is employed than might have been supposed. They infer that restraint is too largely employed in the United States, and that we are behind other countries in this respect, especially Great Britain. They believe, however, that non-restraint is carried beyond reasonable limits in some English institutions.

New Inventions, etc.

AN IMPROVED WASTE-PIPE TRAP.

The device shown in the following cut is a very simple mechanism, being nothing more than an S-trap with the addition of a valve.

It is made wholly of brass, and is easily applied to any waste-pipe. It is so constructed, too, that access may be had to its interior by using no more complicated tool than a nail. It is maintained by the manufacturer, Mr. H. P. Clement, that it is proof against siphoning, and against regurgitation of gas from pressure, thus doing away with

the necessity for ventilating pipes. From our own observation, and from the experience of several well-known members of the profession in its use in their own houses and in hospitals, we regard it as a most manageable and effective device.

Miscellany.

AMIDE BODIES AS ANIMAL NUTRIMENT.—At a meeting of the Physiological Society of Berlin, on June 16th, Professor Zuntz read a paper upon the value of amide bodies as animal nutriment, based on experiments which he made upon a number of rabbits. In each experiment he divided the animals that he was experimenting on into two groups. One of these groups was fed with food-stuffs containing no nitrogen (starch and oil), and with various nutritive salts, while the other rabbits received, in addition to this food, a supply of amide bodies. The object of the experiments was to determine which, if any, of the amide bodies could replace the albumin of the food. Herr Zuntz managed to overcome the distaste of the animals for the monotonous, unstimulating diet (a difficulty which has often to be combated in a disagreeable manner in experiments of this kind), by also giving them small quantities of an alcoholic infusion of hay, and by giving the food that had been refused by the animal as pap or powder, in a firm friable form. The results of the experiments may be shortly summed up thus: Extract of meat, when added to the non-nitrogenous food-stuffs, produced no effect upon the nutrition; the animals died in exactly the same time as without the extract. Asparagine likewise could not take the place of the albumin of the food, but the loss of albumin was about twenty per cent. less in the animals that were fed with the asparagine, in addition to their other food, than in those who were fed on non-nitrogenous food alone. An addition of a mixture of asparagine and some other amide bodies—i. e., leucine, tyrosine, and others, of which one might have presumed that they would together form an albumin material during the process of digestion—had, as a fact, the exactly opposite effect of producing a remarkably larger loss of albumin than the non-nitrogenous diet of the other group of animals that were kept for purposes of comparison. In the same way the addition of the crystallizing decomposition products of albumin which were got by the action of pepsin, had a prejudicial influence, producing a greater loss of albumin. Probably an ammoniate was the active principle in both cases, as it is known to work destructively in the body upon albumin; but it is possible that the amide bodies themselves behaved like ammoniate. These experiments are to be pursued with other amide bodies and with decomposition products of albumin.—*British Medical Journal*.

CAMPORATED SULPHUR LOTION.—In the "Gazette Hebdomadaire de Médecine et de Chirurgie," M. Pierre Vigier recommends the following modification of the *lotion au soufre et au camphre*: Rose-water, 250 parts, by weight; spirit of camphor (*alcool camphré*), 30 parts; precipitated sulphur, 20 parts; powdered gum, 8 parts.

This, he states, remains a homogeneous mixture for a considerable length of time, and, when in course of time the insoluble constituents have settled, may again be made uniform by gentle agitation.

THE SOY BEAN.—Professor E. Kinch, writing on the subject of the soy bean (*Soja hispida*) in the July number of the "Agricultural Students' Gazette" (Royal Agricultural College, Cirencester), says: This bean, of which there are a dozen or more varieties known in the East, is very largely used as an article of food in Japan and China, where it is manufactured not only into soy, now exported in considerable quantities to Europe, but also into bean-cheese and other forms of food. The soy bean, in its proximate composition, approaches more nearly to animal food than any other known vegetable production, being singularly rich in fat and in albuminoids, and it is therefore a valuable adjunct to the food of the almost vegetarian Japanese. Of late years, especially since the Vienna International Exhibition, many efforts have been made to acclimatize this bean in various parts of the European continent, chiefly in Hungary and Germany. France and Italy have

also attempted it, and some of the experiments have been fairly successful. "Nature" states that Professor Koch is trying to grow some of the varieties in the botanic garden at Cirencester, and though our climate is probably too uncertain, and the temperature often too low, for most of the varieties to attain perfection, still, if any of them could be acclimatized, a valuable leguminous cross would be added to our present list. A detailed analysis is given of the bean as grown in different countries, of several of the foods made from it, of its straw, which is a useful fodder, and of the ash of the bean and straw.—*British Medical Journal*.

VIRUS-ATTENUATION RUN MAD.—Truly, M. Pasteur's doctrine of the attenuation of viruses goes apace; for now Professor Bouley, one of its most enthusiastic partisans, comes forward with a proposal for its extension to small-pox itself. He selects Algeria as a fitting field of operation, and, in a paper just read to the Académie de Médecine, proposes that the Arabs, who have great objections to vaccination, but none at all to inoculation, should be inoculated with the dilute or attenuated virus. The proposition, we are glad to find, was received with almost a storm of disapprobation, so that this fluent speaker had some difficulty in getting his views listened to. To it was objected that the evil for which it was thus proposed to find a remedy is grossly exaggerated, for the Arabs, devastated by epidemics of small-pox, and witnesses to the efficacy of vaccination in their vicinity, have in large numbers abandoned their opposition, and undergo vaccination in great numbers. Moreover, the assisting to keep alive this dangerous virus with all its contagious properties, and the discouragement given to the practice of vaccination—which, whatever may be the case in the country of its origin, has few opponents in France—sufficiently condemned the proposition.—*Medical Times and Gazette*.

LESIONS OF THE TEETH IN LOCOMOTOR ATAXY.—At the meeting of the French Association for the Advancement of Science, on August 30th, a communication was made by M. Th. David upon lesions of the teeth found in locomotor ataxy. The paper was based upon the observation of a single case, and the following are the most important of the conclusions arrived at from an attentive study of it. The alteration consisted of a rapid decay of the anterior part of the crown of almost all the teeth. The altered substance assumed the consistence of touchwood and a reddish color. The enamel still retained its polish, but not its hardness. Beneath those parts the pulp had produced a new layer of secondary dentine, and in most of the front teeth the pulp-cavity was filled up. These alterations had nothing in common with caries, and must be referred to nutritive disturbance resulting from the lesion of the central nervous system. The changes are analogous to those which have already been observed to take place in the nails in the course of locomotor ataxy; they would thus establish a pathological relationship between organs already connected by a common epithelial origin. Locally, these alterations recognize for their immediate cause a functional disturbance or a lesion of the dental pulp. The atrophy which has been shown to exist would be quite comparable to that which is observed in the eye under similar circumstances. Whence the final conclusion that we must attribute to the dental pulp the physiological significance of a sensory organ.—*Medical Times and Gazette*.

A NEW ANIMAL FOOD.—Is the capybara really good to eat? Dr. Saec strongly recommends it for cultivation and domestication, alleging that it is an excellent acquisition for farms and country houses, where, without requiring more care than a rabbit, it will supply as much meat as a sheep, and he believes that it will take a place between the sheep and the pig in Europe, and that, in many ways, it can be substituted for the last-named domestic animal. This capybara, which is found in great abundance in South America, is of the average size of a pig; it can be obtained very easily; it quickly recognizes its master, whom it follows everywhere, and eagerly seeks for caresses. It especially likes to be scratched, and, to attract attention, extends itself full length on one side. It is very clean in its habits. In shape the capybara realizes the normal type of the meat-producing animal, as its body is an almost perfect cylinder; its limbs are short and slender; its tail

and ears are very short; the head alone is large. Its apathetic character makes all nourishment available which it consumes, so that it is not necessary to fatten it; and it can be kept in a limited space. It will thrive in a dry stable, where it should be fed on all kinds of vegetables, herbs, and roots; it likes clean water and a soft litter, and it eats remarkably little for its size.—*British Medical Journal*.

VASO-MOTOR PHYSIOLOGY.—The vaso-motor effects which are produced by faradaic stimulation of the peripheral segment of the lingual nerve have been lately studied by M. Vulpian. This stimulation is well known to cause a considerable dilatation of all the vessels of the corresponding half of the tongue in the region in which this nerve is distributed. The experiment is easily performed on a dog under the influence of morphia, or which has been curarized and subjected to artificial respiration. The mucous membrane in this region, and also on the corresponding side of the frænum, becomes bright red, and a similar change may sometimes be observed in the mucous membrane of the gum on the inner surface of the lower jaw near the canine and incisor teeth. The principal vein of this part of the tongue becomes turgescient, and the blood contained in it and its tributaries becomes bright in color, resembling that of arterial blood, while there is a corresponding rise in the temperature of the part. These phenomena are produced sometimes after the lingual artery has been tied, and even after the internal and external carotid arteries of that side have been tied just above their origin, and the carotid itself has been tied in the middle of the neck. Nor are they prevented even by the ligation of the common carotid and the vertebral. The effects are equally marked after the section of the vago-sympathetic trunk, and after excision of the superior cervical ganglion. When the circulation has been definitely arrested, as by the farado-puncture of the animal's heart through the thoracic wall, the opposite half of the tongue becomes pale before that on which the lingual has been faradized. Thus the effect of the stimulation is opposed to the occurrence of the constriction of the vessels, which occurs throughout the body almost immediately after death. Another remarkable fact noted by Vulpian is that at the moment when the dilatation occurs, in consequence of the faradization of the nerve, there is a distinct contraction of the vessels on the opposite half of the tongue. It is not merely the result of the determination of blood from one half of the tongue to the other, but is the effect of a distinct activity of the vaso-constrictor nerves, for there is a distinct darkening of the blood. This condition, however, does not last so long as the dilatation of the vessels on the faradized side. The latter may continue for ten minutes, while the former has disappeared in half a minute. This vaso-constriction appears to be reflex, for it is far less conspicuous if the vago-sympathetic trunk on that side has been previously divided. The lingual nerve seems thus to possess a certain amount of recurrent sensibility, which is manifested by this reflex action when the peripheral extremity of the divided nerves is stimulated.—*Lancet*.

FOOD MAKES THE MAN.—Speaking roughly, about three-fourths, by weight, of the body of man is constituted by the fluid he consumes, and the remaining fourth by the solid material he appropriates. It is therefore no figure of speech to say that food makes the man. We might even put the case in a stronger light and affirm that man is his food. It is strictly and literally true, that "A man who drinks beer thinks beer." We make this concession to the teetotallers, and will add that good sound beer is by no means a bad thought factor, whatever may be the intellectual value of the commodity commonly sold and consumed under that name! It can not obviously be a matter of indifference what a man eats and drinks. He is, in fact, choosing his animal and moral character when he selects his food. It is impossible for him to change his inherited nature simply because modifications of development occupy more than an individual life, but he can help to make the particular stock to which he belongs more or less beefy, or fleshly, or watery, and so on, by the way he feeds. We know the effect the feeding of animals has on their temper and very natures; how the dog fed on raw meat and dressed up so that he can not work off the superfluous nitrogenized material by exercise becomes a savage beast, while the same creature fed on bread and milk would be tame as a lamb. The same law of results is applicable to man, and every

living organism is propagated "in its kind" with a physical and mental likeness. This is the underlying principle of development. Happily the truth is beginning, though slowly and imperfectly, to find a recognition it has long been denied. It is possible that in the natural desire to secure the best and purest supplies of food and drink for man we are pushing matters a little to extremes and becoming ridiculous. Utopia is a long way off, and "Hygeia" has not yet been built. It is, however, desirable that we should aim high and make the teachings of physiological science the precepts of our daily life and conduct. We may not be able to reach our ideal, but progress will be advanced by striving to make its attainment an object. "What to eat, drink, and avoid" is a rational proposition; and if some of us are becoming a little unreasonable in the attempt to solve it, at least we are on the right road, and ought to be encouraged rather than abashed by the not unkindly criticism our endeavors are calling forth.—*Lancet*.

THE CRIMINAL SPREAD OF INFECTION.—Judge Dixon, of New Jersey, in a recent charge to the grand jury of Paterson, called their attention to the case of a man employed at the pest-house in that city as nurse to a small-pox patient, and who, having the germs of the infectious disease about him, went recklessly to his family, communicating the disease to his children, one of whom died. In commenting on this case he said: "If a man, conscious that he carries about with him the germs of a contagious disease, recklessly exposes the health and lives of others, he is a public nuisance and a criminal, and may be held answerable for the results of his conduct. If death occurs through his recklessness, he may be indicted for manslaughter. It is held that where a person knowingly communicates a contagious disease to another and death results, the crime is that of manslaughter." Judge Dixon furthermore added: "The man may be indicted also for spreading the disease by conscious exposure of others thereto by his presence in public places, such as on the streets, in halls, etc. He might be indicted as a public nuisance for endangering the public health in this way even if no consequences had followed. The law provides some penalty for such offenses against the public safety."—*Boston Medical and Surgical Journal*.

RECOVERY FROM HYDROPHOBIA.—At a recent meeting of the Paris Academy of Medicine a memorandum was read by M. Decroix, reporting nine cases of cure of hydrophobia. The Committee on Rabies made, during the year 1874, a series of experiments with medicines said to be useful for curing rabies, in which they made use of pilocarpin three times, and in every case the remedies hastened death by the violent fits they brought on. In the course of his experience M. Decroix met with two cases of rabies which did not end fatally. The conclusions arrived at by the committee are as follows:

First. It has been experimentally demonstrated that rabies may recover spontaneously.

Second. Up to the present no treatment has proved to be antihydrophobic, and cases of cure by this or that means may be attributed to the efforts of nature.

Third. All the means used by the committee since 1874, comprising principally injections of pilocarpin, have hastened rather than retarded the death of the subject.

Fourth. Those dogs usually recovered which were left without treatment, as the medicines brought on violent fits, and there is an inclination among medical men to leave men thus attacked in perfect quiet, and only practice experiments on animals. The filing down of dogs' teeth—an easy and almost painless operation—is still the most efficacious preventive of madness.

Fifth. Rabid people left in the dark and kept quiet are not subject to fits, unless they are brought on by excitement or by ordinary medicines, and, "as far as I am concerned," says M. Decroix, "I would rather be attacked by this kind of madness than many other diseases, particularly than that red chance of smokers."—*Medical Press*.

On Mondays, Wednesdays, and Fridays, at twelve o'clock, during February, March, and April, Dr. J. L. Little will continue his surgical clinic at the New York Post-Graduate Medical School, 213 East Twenty-third Street.

A NEW HAIR-DYE.—The disadvantages attending the use of hair dyes containing lead, and the positive danger attending their use, have induced M. Naquet to search for a liquid which may be used for dyeing the hair, and yet be innocuous. He describes, in the "Moniteur Scientifique," a dye which is said to have a progressive action, to produce all shades up to a deep chestnut-color, and yet to be free from all deleterious action. The base of the dye is bismuth. The following is the formula. Bismuth is dissolved in the smallest possible quantity of nitric acid—nearly three parts—and to this liquor a solution in water of tartaric acid, equal in weight to one fourth of the bismuth used, is added, and then a large quantity of water, so as to insure thorough precipitation of the bismuth. The precipitate is filtered off, and washed with water until the washings have lost all acidity. The precipitate is dissolved in a solution of ammonia; and, for this rather more than a fluidounce of solution of ammonia will be required for each ounce of bismuth used. Hyposulphite of soda—three fourths of the weight of the bismuth employed—is then added, and, when the salt is dissolved, the mixture is filtered, and preserved in well-closed bottles. The dye should contain about one twentieth of its weight of bismuth. Such a mixture is said to form an admirable dye, which loses ammonia on exposure to air, and deposits sulphide of bismuth.—*British Medical Journal*.

THE HYGIENIC PROTECTION OF PARIS CHILDREN.—By recent decrees it is forbidden to employ boys under sixteen years old, or girls under eighteen, to furnish the power for hand-looms. Boys between twelve and fourteen years of age, and girls between twelve and sixteen, must not be made to draw loads on the highways; but this is allowed on the level floors of manufactories, etc., provided the load and the vehicle together do not weigh more than 100 kilogrammes. Boys only, when over fourteen years old, may be employed to haul loads on the highway, provided the load and vehicle together do not exceed 100 kilogrammes in weight. Tilers and plumbers are forbidden to employ children on roofs.

HYDROCYANIC ACID IN ALBUMINURIA.—In a letter to the "Lancet," Mr. V. G. Webb states that some five years ago, having ordered full doses of hydrocyanic acid to allay vomiting for a patient with diptheria, he found the next day that the percentage of albumin in the urine was reduced one half; also that he has lately found the drug equally beneficial in scarlatinal nephritis.

THE MARYLAND MEDICAL JOURNAL.—With the number for January 1, 1883, this excellent journal was increased in size by the addition of eight pages to each number.

IODIDE OF BARIUM.—Mr. T. M. Kendall, of New South Wales ("Brit. Med. Jour.," Oct. 2, 1882), remarks that this drug, being very poisonous, must be used with caution. He has found it useful in certain cases of chronic eczema, in the form of an ointment made with vaseline, particularly in old cases with much infiltration. In acute cases it aggravates the inflammation.

THE MEDICAL BOARD OF CHARITY HOSPITAL.—The following officers were elected at the annual meeting of the Medical Board of Charity Hospital for the current year: President, Dr. J. H. Ripley; Vice-President, Dr. J. F. Ferguson; Secretary, Dr. Edward S. Peck.

Our French exchanges note the abrogation of the decree by virtue of which the retirement of college professors has been enforced on their attaining a certain age.

ARMY INTELLIGENCE.—*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 30, 1882, to January 6, 1883.*—GORGAS, W. C., Assistant Surgeon. Relieved from the temporary duty to which assigned under Par. 4, S. O. 137, Department of Texas, and will report to the commanding officer, Fort Brown, Texas. Par. 2, S. O. 140, Department of Texas, December 26, 1882. — McKEE, J. C., Surgeon. To report on or before January 1, 1883, to the commanding officer, Fort Winfield Scott, California, for assignment to duty as Post Surgeon. Par. 1, S. O. 197, Department of California, December 28, 1882.

Lectures and Addresses.

LECTURES ON
HUMAN AUTOMATISM.

DELIVERED AT THE LOWELL INSTITUTE, BOSTON.

By WILLIAM B. CARPENTER, M.D., LL.D., F.R.S., Etc.

LECTURE II.

Congenital or Primary Automatism in the Bodies of the Lower Animals and of Man. Mechanism of Reflex Action. Provision made by it for the Maintenance of the Organic Functions. Morbid Forms of Reflex Action.

In the more detailed discussion of the subject of human automatism on which we are now to enter, I think it just as important to make you perceive what automatism *does*, alike in our corporeal and in our mental nature, as what it *does not*. And it is my intention in this evening's lecture to place before you, in a somewhat connected shape, a general outline of our knowledge of the automatism of creatures below us in the scale of organization, beginning with some of the lowest and simplest plants, and thence ascending gradually to man. The automatism of man may be considered as partly *original* or *primary*, and partly as *secondary* or *acquired*. In this evening's lecture I shall confine myself to those of his actions which are *originally* automatic; and we shall find that all these are subservient to the maintenance of his organic functions, whose continuous performance is essential to his life.

I pointed out to you in the last lecture that if we could conceive a being to be made up only of bones and ligaments, with muscles to move them, and with a nervous system and organs of sense, and if such a being were capable of sustaining itself, that fabric would really constitute *the man*; but that, as such a fabric could *not* sustain and exert itself (a combination with a number of other organs being requisite, first to build it up, next to keep it in working order, and then, to provide the force to work it), considerable assistance must be given by the nervo-muscular apparatus in the labor of that part of our organization. And we shall find that the primary or originally automatic actions of man are entirely concerned with that part of his life which consists in vegetative or organic activity—the provision and application of food-supply and the elimination of waste-products. In the lower tribes of animals, on the other hand, we find that the *whole* life may be regarded as automatic, there being nothing above the purely *physical* automatism which shows itself in plants. But, as we rise in the series, we shall find super-added to the purely physical automatism what we may call a *sensorial* automatism, in which the excitement of consciousness forms a necessary link. And we shall then ascend into a yet higher grade, in which something like *rational* automatism is apparently exhibited, and in which *feelings* somewhat resembling our own would seem to take part. And, when we rise still higher, we find this rational automatism gradually attaining more and more of an intellectual character, the processes of reasoning becoming more

elaborate and complex, taking a larger and larger part in the animal's life, habits, and conduct, and prompted by feelings and emotions which show a very marked approximation to our own.

I shall commence by adverting to the automatism of some of the very lowest and simplest forms of vegetable life—certain little water-plants which grow, I suppose, in your streams as they do in ours, as thread-like filaments (*Conferve*), which attach themselves to stones in running streams; and also the broader expansions of such filaments which form the grass-green sea-weeds (*Ulve*) that are very common upon most shores, some of them narrow like blades of grass, some of them spreading out into broad, flat, and very thin expansions, each consisting of only a single layer of cells. All these belong to the same general low type of vegetable organization, the different parts being mere repetitions of each other, without any differentiation (as far as we yet know) even for fructification. At a certain stage of their existence the green matter contained in their cells aggregates into little separate bodies; and we can see these with the microscope actively moving about within the cells. If you find one of the grass-green bands of an *Ulva*, attached to a stone on the sea-shore, with its terminal portion colorless, and examine it microscopically at the border of its green portion, you will probably see the very curious spectacle which utterly astonished me when I first witnessed it forty years ago. The white portion being that from which these green particles have already been discharged, the cells at the border of the green portion are in the act of discharging them; and you may see the green particles issuing in numbers through apertures in the cell-walls, and swarming in the drop of water into which they have thus escaped. These motile particles we call zoospores, the term "spore" being applied to the reproductive particles of these plants, and the prefix "zoö" meaning that they have an activity of motion which makes them resemble animals. These "zoö-spores," in some instances, have vibratile *ciliary* filaments (so named from their resemblance to eyelashes) radiating in great numbers from every part of their globular surface; in other instances they are moved by the "lashing," of a single, long, whip-like *flagellum*. In either case, the motile organs are prolongations of the protoplasmic substance of the interior of the spore; and it is by the contractility of this protoplasm, exactly as it is by that of the similar protoplasmic filaments in the lowest tribes of animals of which I shall presently speak, that these active movements are produced.

Now, it is a singular and interesting thing to find this wonderful animal-like activity in what are unquestionably vegetable particles. When these remarkable movements were first noticed by a naturalist of the last century, Vaucher—whose name has been given to the plant in which he observed them, now known as the *Vaucheria*—he very naturally described the organism as a *plant* in one period of its existence and an *animal* in the other. We now, however, know of so many instances of vegetable movement that we do not regard it as indicating any affinity, in the minute "zoöspores" of aquatic plants (which such movements serve to disperse), to the animal kingdom; and I may give

you another rather striking example of them in the "motile" state of the minute unicellular plant *Protococcus pluvialis*.

It happened to me, thirty-five years ago, to notice in an open cistern outside my house, which had been newly filled by a thunder-shower with rain-water, that, when the sun shone upon its surface, the water became covered with a green scum, which rose into bubbles. These, I felt sure, were bubbles of oxygen, given off by the decomposition of carbonic acid produced by the action of the green matter under the influence of light; and as that is one of the most characteristic phenomena of vegetation, any organism which exhibits it must be regarded by the physiologist as almost unquestionably belonging to the vegetable kingdom. Yet when I took up some of this green scum and placed it under the microscope, I at once saw that it was composed of separate particles, each furnished with a *flagellum*, by the lashings of which every individual particle was kept in a state of most active motion. Yet at that time Professor Ehrenberg, whose authority was of the highest among microscopists, had described and still maintained that this *Protococcus*, whose vegetable nature no one any longer doubts, was an animal; and he also maintained the animal character of what almost every microscopist now accepts as a vegetable, that beautiful *Volvox*—a transparent sphere, dotted over with green points, and having an incessant rolling motion—which is found in many ponds, and is, doubtless, familiar to many of you. Every one of these green points is an independent vegetable cell, with two *flagella*, which are in continual vibration; and the combined lashing of these keeps the whole globe in a state of incessant motion, rolling it sometimes in one way and sometimes in another across the field of view.

Here, then, is a remarkable instance of a purely physical automatism. There is no nervous system to call forth these motions. They arise entirely from the endowments of the protoplasm contained within the vegetable cell, which extends itself into the motile filaments, either *cilia* or *flagella*.

We will now pass from these to a higher form of vegetable automatism, which will, I think, be yet more instructive. I refer to such movements as you may see performed by the sensitive plant (*Mimosa sensitiva*), and by the Venus's fly-trap (*Dionaea muscipula*). In the case of the sensitive plant, touching any one of the leaflets, when the plant is in a state of full activity, is sufficient, first, to cause the folding together of the set of leaflets upon its own pinnule or division of the midrib, and then to produce a like closure of the leaflets on other pinnules arising from the same midrib; and the effect of the irritation further extends to the base of the leaf-stalk itself, the entire leaf suddenly bending down. This condition usually lasts for some little time; and then the leaf-stalk rises, the pinnules unclose, and the leaflets spread out again.

The Venus's fly-trap has a leaf consisting of two broad expanded lobes, with prickles upon the surface of each; and it is sufficient to touch either of these prickles for the lobes to fold together, so that the sharp spines which project from the edge of each cross those of the other, inclosing any unfortunate insect that has alighted upon the leaf. You are all probably aware that this is one of the remarkable cases

investigated by Mr. Darwin, of the feeding of plants upon animal substances, which undoubtedly minister to the life and growth of those particular types of vegetation.

Now, in the Venus's fly-trap, as in the sensitive plant, the contraction is not in the part which is itself irritated, but in a distant part, the touching of one of the thorns that project from the surface of either leaf-lobe producing a contraction in the hinge-joint by which the two leaflobes are connected, and causing them to close together; and there is reason to believe, from recent investigations, that, in this and similar cases, the communication between the part touched and the part which contracts is effected by a continuous, or nearly continuous, thread of protoplasm, passing from cell to cell. The nature of this communication is now being made the subject of extremely careful study, both in Germany and in England, with the aid of the most delicate methods of investigation that can be brought to bear upon it. And I believe the conclusion to be a probable one, that we have here something which may be said to be an incipient nervous system. As we shall hereafter see, the essential part of the nervous system of any one of the higher animals, as of our own, is an intensified protoplasm, the function of which, in its simplest form, is purely *internuncial*—transmitting from an *impressible* part the effect of a stimulus applied to itself toward a contractile part which moves in response thereto. Thus, in the sensitive plant and Venus's fly-trap, we seem to have a distinct foreshadowing of the lowest form of proper "animal" automatism—"reflex action" of that purely physical kind which is altogether independent of consciousness.

Commencing, however, with the movements of the simplest animalcules, we find their conditions to be essentially the same as those of the vegetable zoöspores—with this difference: that their food, instead of being obtained by the action of light, which enables the plant to elaborate it for itself out of the water and air in which it lives, consists of material already thus prepared, which is for the most part received bodily into the interior of the cell. I will not say that this is a *universal* distinction; but it is certainly the most *characteristic* distinction between the animal and the vegetable, that while the vegetable can combine oxygen, hydrogen, carbon, and nitrogen into such "organic compounds" as starch and protoplasm, the animal is dependent upon organic compounds which are made for it by the plant. And this distinction we find very obvious in a large proportion of what we now designate as true animalcules, separating from Ehrenberg's animalcules a large group which are undoubtedly to be transferred to the vegetable kingdom.

Some of our simplest forms of animalcules are individual cells, each having a definite opening in its cell-wall, through which food-particles are driven into its cell-cavity by the lashing action of the ciliary filaments with which it is beset, these cilia also producing the movement of the animalcule through the water that brings it within reach of the vegetable particles or minuter animalcules on which it lives.

Now, to what are we to liken these animalcules? Are we to consider them as endowed with consciousness, with will, with any of our higher mental attributes? I think certainly not. I believe that the only safe method is to

look out in ourselves for their nearest analogues, and not to credit these simple forms of animal life with any higher attributes than what we find in the corresponding parts of our own bodies. Now, ciliated cells are found clothing the membranous wall of our own internal respiratory passages; from that which lines our nostrils, passing thence through the windpipe, and being thence prolonged throughout the "bronchial" tree in the interior of each lung; and though not swallowing food-particles, but imbibing liquid nutriment from the blood-vessels of the membrane on which it rests, each of these ciliated cells maintains an independent existence, and helps to keep up, by the action of its own cilia, a constant movement over the whole of the respiratory surface, by which its fluid secretion is continually urged toward the outlet of the system of tubes, instead of accumulating and blocking up the interior.

There is another type of about the same grade, of which we have a still more remarkable parallelism within ourselves: this is the *Amœba*, one of the simplest forms of that "Rhizopod" type by which are produced those beautiful minute shells that we term *Foraminifera*.

This *Amœba* is a jelly-speck, which is found in most ponds, and is familiar to almost every microscopist; it is a very sluggish kind of creature compared with the ciliated animalcules; but the watching of its movements is extremely interesting. By the contractility of its protoplasmic substance it is constantly changing its form, and creeping across the field of the microscope; and it also takes in animalcular particles into its own substance, from time to time, not through any definite mouth, but by an extemporized passage into the interior, the ectoderm or outer film of protoplasmic substance being everywhere so soft that there is only a little difference between itself and the rather more liquid interior portion. Thus, any particle over which the creature moves can be received by a sort of gaping at that particular point, the formation of an extemporized mouth leading into the cavity; and in this cavity it undergoes digestion, its nutritive part being appropriated, while, if there be any hard portion to be rejected, this passes out of the superficial layer by an extemporized orifice of exit.

Now, it may surprise many of you to learn that our blood contains immense multitudes of very similar particles. I do not refer to the red corpuscles of the blood, but to the white or colorless corpuscles; for it is one of the most interesting of modern discoveries made by the microscope, that, if we get some of these under view, and keep our glass slide sufficiently warm so as to maintain them at the temperature of the body, we may see, on watching them for an hour or more, most *Amœba*-like changes in them, and even the reception of particles into their interior, as in the *Amœba*. On what ground, then, are we to credit the *Amœba* with any higher attributes than those we know to exist in these colorless corpuscles of the blood? I think we may say that they are creatures of pure automatism. They have a separate existence, they float in the blood-streams, and each passes through a life of its own; and that life contributes in some way not yet understood to our own general life.

There seems to be another form of the same type in our own bodies—the cells at the extremities of the intestinal

villi—the little rootlets through which the nutrient materials provided by the work of digestion are selected and passed on into our absorbent vessels. For it has come out very clearly of late—in the careful investigations which have been made upon the interior structure of the *Hydra*, the common fresh-water polyp, and other forms of the same type—that their digestive cavity has a lining of *amœboid* cells, and that these cells really do the work of absorption, selecting from the products of digestion from the cavity of the stomach, and communicating those products to the other layers which form the walls of the stomach and body. This is a very curious and interesting consideration, and shows how even the body of man is an aggregate of separate existences, each living and acting for itself, and yet all contributing to do his work for him.

Let us go a little higher, and look at some of the more remarkable actions of some of these lower animals, which have a very definite and rhythmical type of movement. I dare say that most of you have seen some forms of the common jelly-fish, and have remarked how they swim through the water with a sort of flapping action, which might remind you of the beating of the heart. Now, this is truly a rhythmical automatism, a movement taking place at regular intervals, which is sustained by the animal's own mechanism. And it has recently been clearly determined that there is here a distinct separation between nerve and muscle; that we are no longer concerned with a homogeneous contractile substance which is (so to speak) both nerve and muscle alike, at once receiving impressions, and responding directly to those impressions, as is the case with the low protoplasmic creatures whose actions we have previously considered; but that there is in one part a substance which receives the impression, and in another part a substance which is called into contraction by that impression through the "internuncial" action of threads of intensified protoplasm, which constitute a low form of nervous system. Mounting a step higher, I may call your attention to an animal which has been for many years a subject of my own special study—the *Comatula*, or "feather-star," which is the commonest type on temperate shores of that great group of *Crinoids*, or "stone-lilies," which, though chiefly known in a fossil state, has been shown by recent researches to be still living at considerable depths in various parts of the oceanic area. The peculiarity of the *Comatula* is that, although in its early state a stalked crinoid, attached at its base to a fixed support, it falls off this stalk at a certain stage of its growth and becomes a free swimming star-fish. The ordinary star-fish, you know, are very sluggish creatures; but this "feather-star" (so designated by my old friend, the late Professor Edward Forbes, who first brought it into special note among us) has a remarkably active, free swimming movement. Instead of having the thick arms of the common star-fish, which are really divisions of the body, it has a central body and five primary rays, each of which divides into two arms, so that there are ten arms altogether; and it is a most interesting and beautiful thing to see the manner in which this creature swims. The alternate arms—we might say all the right and all the left arms, if the creature had right and left sides—move together, the right arms

first arching up like a swan's neck, then turning down again, and then bending backward; and then the left arms doing exactly the same, with the most perfect rhythm and symmetry. In this creature there is the most perfect division between nerve and muscle. The skeleton of every arm is composed of a gradually tapering series of hundreds of similar calcareous segments; and these segments are (so to speak) hinged one upon another, with a pair of muscles interposed *above* the hinge between each and the next. These muscles are all flexors, bending the successive joints upward one upon another, so that, by their consentaneous action, the arm is coiled into a regular spiral, resembling a watch-spring. These flexor muscles are antagonized by an elastic ligament passing *below* the hinge between each segment and the next, and the action of these is to straighten the arm out again when the muscles are relaxed. Now, I have carefully experimented upon this "feather-star," and I have satisfied myself completely that there is a definite central nervous system from which the stimulation proceeds to these flexor muscles of the arms, and have found it a most interesting problem to work out the particular mode in which that nervous system operates. I must not detain you with any details upon this subject, but merely tell you that we have in this creature one of the most beautiful examples of a rhythmical and concentric action of hundreds of pairs of muscles all working together automatically under the general direction of a central nervous system.

These "feather-stars," like other animals of the *Radiata* type, have all their organs equal and similar to one another; there are no eyes to direct the animal in any particular course; there is nothing that can be called a head, nothing that can be called a tail; their limbs, in swimming, move equally all round; and, when they fix themselves and expand their arms, a little irritation to the tentacles round the mouth will cause the whole of the arms to shut up together, as if to protect the mouth, and then gradually unclosing when the irritation ceases. It is a singular proof of the pure automatism of these movements that I have often noticed that an arm which has been thrown off (a frequent occurrence with these animals), and which has lain in a saucer of sea-water for several days, coiled up in a spiral, has sometimes suddenly uncoiled, and has as suddenly coiled up as it was before, by the alternating action of the ligaments and the muscles, without any obvious cause.

(To be concluded.)

Original Communications.

REGARDING THE NORMAL POSTURE OF THE ADULT UTERUS.

By ANDREW F. CURRIER, M.D.

It would appear to the minds of many that this question was long ago settled. Schultze assumes that he has established the only correct view of the matter ("Zur Klarstellung der Indicationen für Behandlung der Ante- und Retro-versionen und -flexionen der Gebärmutter," Leipzig, 1879), but Fritsch has surpassed him, and gives as the

normal posture of the organ an inclination which implies one of two things—either that the German women, in *their native land*, are differently constructed from the American and English women (admitting the accuracy of Fritsch's observations and examinations), or the perceptions of English and American gynecologists have been dull, and their work has been of a stupid character. The examination of the uterus and its relations upon the dead body does not reveal to us the same facts which are obtained by an examination of the living. The organs and tissues in the dead body are stiffened and contracted, and the uterus itself becomes retroflexed within twenty-four hours after death (Schultze, *op. cit.*), supposing the subject to have been placed upon the back, as is usually the case, and the uterus to have been in a normal posture at the time of death. If the examination be made during life, on the other hand, the impression conveyed by the touch will vary according as the patient is examined in the standing position, upon the back, upon the left side, or upon the hands and knees, unless the organ is fixed by inflammatory deposits, or is deformed in some way. Therefore, the desirability is obvious that writers upon this subject fix upon some standard, as it were; that is to say, some posture which will always be assumed in descriptions of the natural posture of the organ. This will prevent confusion, especially in the minds of beginners, for it should be the aim of teaching to make its definitions as exact as possible; indeed, formulated knowledge can lay claim to the title of science only when established upon such a foundation. What, then, are the tissues and organs which constitute the environment of the uterus when in a condition of health; what the forces at work to keep the organ in a condition of equilibrium? For an answer to the first part of this question there is no recourse but the study of the dead body; by reasoning upon the principles of mechanics we can reach an answer to the second part. If we obtain a transverse pelvic section of an adult female, prepared, perhaps, as Braun prepares his beautiful frozen sections, we find the uterus a center toward which all the surrounding elements converge and contribute. Truly nature has provided generously for that part of the organism where such wonderful work is accomplished—the bladder in front, the rectum behind, areolar tissue where requisite, the broad ligaments and the Fallopian tubes on either side, and midway or thereabout between the bladder and the broad ligaments the thick round ligaments, with more or fewer muscular fibers, as if backward displacement were an event anticipated and provided for. Examining more closely and at a lower level, the utero-sacral ligaments are seen, extending from the posterior superior aspect of the cervix to the second bone of the sacrum in such a way as to obtain the greatest mechanical advantage; the vagina lies underneath, equivalent to a thick strip of muscular tissue, and it is strengthened upon either side by the fibers of the pubo-coccygeal muscle. In front extend the vesico-uterine and vesico-public ligaments, or, as they have been termed collectively, the utero-pubic ligament (Studley, "Am. Jour. of Obstet.," xii, 39). These two series of structures mentioned are more particularly the attachments of the uterus,

though the vagina is both an attachment and a support. In order to study the basis of support of the uterus, a vertical antero-posterior pelvic section in the median line will be required. The elements which constitute it are the muscles of the pelvic floor, the sacro-sciatic and perineal ligaments, the perineal septum, the perineal muscles, the vagina, the perineal body, and areolar tissue (Studley, *loc. cit.*). To these Hart adds the sphincter ani ("Obstet. Jour. of Great Britain and Ireland," vii, 447), which, when possessing its normal degree of contraction, is capable of no little resisting force.

Next, the forces which regulate the posture of the uterus will be considered. Since the round and broad ligaments are found to be somewhat lax when examined in what appears to be their normal condition, we may conclude that their object is not that of suspension; besides, there is no necessity for such an hypothesis, considering the basis of support upon which the uterus rests. We would infer, from the situation of the organ in a cavity in which it is more or less movable, that the function of these ligaments is a poising one, as in cases where guy-ropes are used. Savage's experiments seem to confirm this idea (Savage's illustrations of the surgery of the female pelvic organs). Should one of the broad ligaments become thickened and shortened, the uterus must of necessity be drawn to that side, disturbing the arrangement of all the forces acting upon the organ, and resulting in misplacement. Should both be shortened, the uterus must of necessity rise in the pelvis. The same mechanical principles must obtain should excessive shortening of the round ligaments occur, excepting, of course, that the force is exercised in a different direction from that which is exercised by the broad ligaments. The utero-sacral ligaments fill a most important rôle, inserted as they are in nearly a vertical direction, and containing as they do unstriped muscular fibers. Having elasticity and contractility, and drawing the uterus upward and backward, they are well called *musculi retractores uteri* (Schultze, *loc. cit.*). Their action is antagonized by the weight of the intestines which is imposed above the uterus, and also by the utero-pubic ligament. In the latter force the bladder itself must of necessity be a sharer. Against the force which the uterus exerts by its weight, in a downward direction, are opposed the structures described as the basis of support. Doubtless some of them are more important than others, but that is not now to be discussed. Suffice it to say that they must exist in their integrity in order to furnish the normal support. To obtain information in regard to the remaining forces which act upon the uterus, a pelvic section is not sufficient. We must theorize in the matter, and the many theories which exist as to the action of the abdominal muscles and the intestines show the uncertainty that is attached to the subject. That the intestines exert an important influence upon the posture of the uterus seems to be overlooked or ignored by some writers. Gravity must compel their descent into the anterior and posterior cul-de-sacs. Their weight, and the pressure of their contents, solid and gaseous, create an opposing force to the movements of the uterus. To this must be added the ever-intermitting action of the diaphragm upon them, and this

force is further complicated by the action of the abdominal muscles. (We see a good illustration of this force in the effort of straining during defecation.) The two sets of muscles work at nearly a right angle with each other, and the resultant of the two forces is one which corresponds practically with the axis of the superior strait, and this force is transmitted through the intestines to the uterus. (That this is the main force in determining the posture of the uterus is seen in the effect of *bearing down* when the organ is prolapsed, or shows a tendency to prolapse.) Thomas mentions as a support, "which is not powerful, but is too important to be overlooked" ("Diseases of Women," 5th ed., p. 369), the anterior projection in the posterior wall of the vagina, upon which the end of the cervix rests, and calls it the "vaginal promontory"; but I have considered this as a portion of the structure of the vagina, and the vagina was mentioned as a part of the *basis of support*. To *sum up*, then, the mechanical forces at work in keeping the uterus in a condition of stable equilibrium are: 1. The support furnished by the underlying tissues. 2. The poising influence of the round and the broad ligaments. 3. The tension of the utero-sacral ligaments, exerted in an upward and backward direction, which is antagonized by the weight of the intestines, by the utero-pubic ligament, and by the bladder. 4. The pressure of the intestines, *per se*, together with the transmitted force from the diaphragm and the abdominal muscles. When the patient is examined while lying in the dorsal position, the finger is able to define the boundaries of the cervix within the vagina, and, to a certain extent, above the vagina. The body of the organ will fall back through several degrees, aided by the displacement of the intestines, and will be out of reach of the finger which is in the vagina. A further source of difficulty in ascertaining the normal posture by an examination in this position arises from the fact that as the body of the uterus falls back the cervix falls forward, not to the same extent, however, for the center of motion does not correspond with the center of the organ. From this it will also appear that the bimanual method of examination will, in very many cases, be ineffective. In many more cases the contraction of the abdominal muscles, and an abundant deposit of fat, will prevent such an examination. (In very few cases would it seem to be possible to carry the bimanual method to the extent which Schultze recommends for the repositing of a retroflexed uterus. Certainly those abdominal walls must be abnormally lax which will submit to such complete *dimpling* behind the uterus.)

In Sims's position, the great advantages in making an examination consist in the use of Sims's speculum and the uterine sound. The error of posture will arise from the dislodgment of the intestines, and the consequent slight anteversion resulting. In the knee-elbow position it is obvious that either ante flexion or anteversion would occur, if the uterus were normally movable. When the patient is standing we have all the forces at work to enable us to ascertain the normal posture. The intestines have gravitated into the cul-de-sacs and about the fundus, the structures forming the basis of support are in a state of rest, and the same applies to the ligaments. Passing in the finger, we

are able to map out the parts with as great distinctness as in any of the other positions, and we have the assurance, from the disposition of the elements which constitute the environment of the uterus, that we can detect its relations with its environment without being compelled to allow much or little for the shifting of one or another force which is a necessity in either of the other three positions. I do not know that it would be possible, or safe if possible, to employ in this position that most useful adjunct, the sound. We have the other positions, however, in which it can be used if desired; but I think one may become so well educated in examining patients in the standing position that he will be willing to risk a statement as to what he has found without reference to the sound or to any other position.

I stated at the outset that Schultze, in the pamphlet to which I referred (his views are further stated in Essays 50 and 176, Volkmann's "Sammlung"), considers that he has established the normal posture of the uterus. It is these views of his, and also those of Fritsch, which are more exaggerated, which it is the object of this paper to criticise. What has preceded has had this end in view. According to Schultze, the anterior wall of the uterus is nearly parallel to the anterior vaginal wall when the bladder is empty. (His diagram, which is reproduced, does not indicate that such is the case.)

the uterus is lifted up, and as it is emptied, the uterus follows it downward and forward, gravity being one cause, when the woman is in the upright position, but the chief one being the intra-abdominal pressure acting upon the posterior surface of the uterus. Thus he considers that the uterus is in a constant state of motion, and that during the

FIG. 2.—Ante-flexion of the uterus, according to Schultze.

emptying of a full bladder it moves through an angle of 48° . If the preceding statements are true, it should always be possible to feel the fundus through the anterior vaginal wall, or, with a sound, through the bladder. Wing has pointed out ("Boston Med. and Surg. Jour.," cvi, 121) that that which is often supposed to be the body of the uterus, "ante-flexed or anteverted," is simply a "sagging" of the organ, to which may be added that in such cases there may be even less flexion than exists, according to Schultze, when the bladder is full. The sound would give useful information in such a case. If the fundus rests upon the bladder, then the anterior cul-de-sac must be empty, and not occupied by intestines, in which case we can conceive that Schultze's views might be correct. We have supposed, too, that the bladder is an irritable organ, and would resist the constant pressure of a solid body upon it. When the uterus is ante-flexed, as Schultze understands ante-flexion (see Fig. 2), and permanently fixed, from whatever cause, there is still greater reason for consequent irritation of the bladder. The portion which is under the fundus uteri does not yield as the organ fills; consequently the latter dilates unequally, and this is pathological. Clinically, we find patients com-

FIG. 1.—Sagittal section through the female pelvis. Normal position of the uterus, with the bladder nearly empty, according to Schultze.

The diagram shows the fundus resting upon the empty bladder, which is said to be normal. As the bladder fills,

plaining of troubles in the bladder when such conditions exist. Why we do not always find this same trouble when the uterus is enlarging during the first months of pregnancy I can not say. In many cases there is great trouble at such times, in others there may be contraction of the broad ligaments, or some other compensating change which prevents harm to the bladder from undue pressure; at all events, the condition *then* is physiological, and I do not know that even Schultze claims that the hinge-joint movement continues until the uterus is free in the upper pelvis. It is therefore necessary to bring other evidence that the bladder would not and does not rebel against the constant pressure of the unimpregnated uterus. Again, if the intestines are not in the anterior cul-de-sac, but lie over the posterior surface of the uterus, that organ being, as Schultze says, in a position nearly parallel (as to its anterior wall) with the anterior vaginal wall, and if the intra-abdominal pressure is the chief force which causes the uterus to fall downward and forward, that force must be exerted through the intestines in a vertical direction, in which case the contractile force of the abdominal muscles is entirely ignored, and the bladder as it fills is compelled not only to raise the uterus, but the superimposed weight of the intestines as well, a quantum of work of which I believe it to be incapable. If the preceding criticism is a just one, it would be superfluous to add very much in regard to Fritsch's views. The accompanying diagram represents his idea of the normal posture of the uterus.

FIG. 3.—Normal position of the uterus. (Fritsch)

He says ("Die Lageveränderungen der Gebärmutter," Billroth's "Handbuch der Frauenkrankheiten," dritter Abschnitt) that the cervix makes with the corpus uteri, when the bladder is empty, an angle of nearly 90°, and that the healthy uterus can be flexed back and forth easily, rigidity

being due to chronic metritis. He also says that if the angle of flexion is greater than a right angle, or if the amount of flexion is not lessened by the dilatation of the bladder or the congestion of menstruation, the condition is pathological. He bases his statements upon the examination of more than fifteen hundred women, in the majority of whom the posture was that which he describes and figures as normal. With the uterus bent at 90°, or even allowing that it recedes somewhat from that, if the examination be made when the patient is in the dorsal position, the use of the sound must be very difficult—much more so than is the usual experience in this country. Think, too, of flexing a woman's uterus back and forth through 180°, and rigidity not resulting. The women whom he examined may have been of that class, which one sees so frequently in German towns and cities, who carry heavy burdens upon the back—tubs of water, bales of rags, and other bulky substances. They are much of the time *bent forward*, and it may be that the constant tension of the abdominal muscles, exerting through the intestines a force working downward and inward, produces the inclination forward of the body of the uterus, which is not the rule here, where women are comparatively seldom seen carrying heavy burdens upon the back. Clinical facts in a matter of this kind are better than no end of theorizing, and these, in so far as I have been able to interpret them, incline me to hold the same opinion as that which is expressed by Barnes, Graily Hewitt, Emmet, Thomas, and other well-known English and American gynecologists, which is that the normal posture of the uterus does not vary greatly from the direction which is taken by the pelvic axis, the body of the organ coinciding practically with the axis of the superior strait. This view also explains satisfactorily, at least to my mind, the action of those forces which are developed around the organ, and which must have a determining influence.

CASES OF BRAIN TROUBLE WITHOUT ORGANIC LESION.*

By GASPAR GRISWOLD, M. D.

CAREFUL pathological investigation has of late years shown us how few cases there are of coma, delirium, or other disturbance of a nature to suggest the brain as its origin, which can not be shown to be dependent upon cerebral lesion, or to which some definite cause can not be assigned, such as uræmia, one of the essential fevers, a poison, etc. Yet cases do even now from time to time present themselves in which we see the gravest symptoms of brain trouble develop without being able to satisfactorily explain their occurrence; and the more we know about the definite causes of such symptoms, the more interesting those few cases become in which we observe *coma*, *delirium*, and the like, as evidences, apparently, of mere functional disturbance. The subject is most aptly introduced by the following histories of cases:

CASE I.—B., twenty-four years of age, single, American, a gentleman, and well educated. He had had no illness since

* Read before the New York Clinical Society, December 29, 1882.

childhood, and was strong and active, and very temperate as regards both alcohol and tobacco. His nervous temperament was intense and excitable, and he had a great fondness for music and art. For two years he had been employed as clerk in a position which imposed upon him great responsibility and required the closest attention. During the last two months he had become a little "run down," had suffered from indigestion and insomnia, and had lost considerably in weight. He was advised by friends to take a vacation, but persisted in his work and consulted a physician, who prescribed five grains of quinine three times a day; this he continued to take up to the time of his illness, but with little benefit. I was first called to see him at 10.30 P. M. August 20th. I found him comatose, though not profoundly; he could be roused to consciousness, but not to intelligence. A servant who was with him told me that he had complained of weariness all day, had eaten scarcely any dinner at 6 P. M., and had gone to take a walk in the evening. He had returned at about 10 P. M., complaining of headache, and had asked for a hot foot-bath previous to retiring for the night. While he was taking the foot-bath he fainted, and was prevented from falling forward by the servant. On closer examination I found his temperature normal, his pulse soft, compressible, and sixty-five to the minute; his respirations were of normal frequency, not stertorous or sighing, or in any way peculiar. His pupils seemed normal, and reacted to light, although he did not flinch when a light was suddenly brought near his face. He could with difficulty be made to protrude his tongue; it did not deviate. The muscles did not anywhere show rigidity or paralysis. His skin was cool and moist; his head was not hot, and carotid pulsation was not marked. His heart and lungs seemed normal, and examination of the urine was negative. The patient was induced to swallow half an ounce of brandy, and in two hours was so far improved that he could converse, although his attention was bad, and he seemed dazed and stupid. A grain of calomel was administered in the form of a Fuller's tablet. In the morning the patient had not materially improved; his mind was still obscured, and he complained of pain in the head and through the eyes. The attendant reported that he had passed a restless night, sleeping little, and tossing about; at times he had been delirious, addressing imaginary persons, etc. The patient, on being assisted to an erect position, staggered, and could not walk without assistance; no tendency to "gyration" or other remarkable movement was observed. The eyes were examined with the ophthalmoscope, and seemed normal; hearing was good, and examination proved that the ears contained no accumulations of wax.

From the date of his first illness (August 20th) until August 25th the patient's condition continued about the same, with morning remissions and evening exacerbations. His mind would be comparatively clear during the forenoon, so that he could answer simple questions and could walk with assistance. During the afternoon his intelligence became obscured, and by evening he was usually more or less delirious. This delirium was exactly like that of fever. He would talk for hours of his business, adding up columns of figures and giving orders about merchandise to imaginary people whom he believed to be in the room. At such times

he could not recognize any one, even his own sister, but would address her as Joe, the porter, or Smith, the cashier, etc. Unless restrained, he would rise from his bed and start for the stairs, saying that he "must go down town," etc. On August 25th he was better in the morning, as usual, but continued to improve during the day and did not become delirious at evening; from that day he had no further trouble, and immediately became himself again. He stated that he had no recollection of anything that had happened since he fainted while taking the foot-bath; the five days during which he had been ill were a blank to him. During the whole time the patient's temperature, pulse, and respiration continued normal, nor did the most careful examinations, often repeated, reveal anything which might point to a cause for his mental condition. It should here again be emphasized that his condition did not resemble insanity, but was exactly like what is usually seen in meningitis, tumor of the brain, or high fever. The patient was also seen by Dr. G. L. Peabody in consultation, and again carefully examined, but without anything being discovered which could explain his symptoms.

No medication was employed except chloral at night. The patient had no appetite, but took milk enough to nourish him. After his recovery, he was quite weak, but gained strength enough within ten days to take a vacation, from which he returned strong and well again. Up to the present date he enjoys good health, and has had no return of his symptoms.

What can be said in the matter of diagnosis? Febrile affections we can exclude at once. The question of possible poisoning may also be dismissed. Among brain diseases we can certainly throw out active congestion, meningitis, encephalitis, and tumor. Diabetic coma and uræmia are also out of the question. As possible conditions we may enumerate cerebral anæmia, an epileptoid seizure, obscurely situated cerebral hæmorrhage, embolism or thrombosis, and lead encephalopathy. The last is certainly improbable, the patient having no colic, wrist drop, or line on the gums, and no history of exposure; moreover, the attack was not attended with convulsions, as is usually the case in lead. The absence of a convulsion is also against the diagnosis of epilepsy; and the dazed condition of the patient, although not unlike that following an epileptic seizure, lasted too long without a repetition of unconsciousness to sustain the resemblance. The patient was very young for cerebral hæmorrhage; but perhaps the theory of a small thrombosis, embolism, or hæmorrhage, so situated as to give no motor or sensory phenomena, is not without plausibility. It is well established that such lesions, situated in the posterior lobe, may give no other symptoms than obscured intelligence, ushered in by a short period of unconsciousness. The idea that cerebral anæmia, dependent upon exhaustion from overwork and insomnia, was the cause of the patient's symptoms, is no doubt the view that most physicians would take of the case; and yet, if this be true, it is certainly strange that the symptoms should continue a week. In most instances the normal circulation of the brain would be restored after a much shorter interval of rest.

CASE II.—W., aged fifty, American, married, and an author and literary critic by profession. A man of temper-

ate habits, but with a very excitable nervous system, inclined to enthusiasm and absent-mindedness. Mr. W. enjoys good health, and is very active; when he has work on hand he is inclined to spend very little time in eating or sleeping until it is finished. About a year ago Mr. W. came to New York on a visit (he lives in Boston), and began at once to rush about and try to see everything that was of literary or artistic interest. On the third day of his visit he was in a glow of excitement, and was out all day, apparently tireless; returning home just before dinner, he sat down to read until it was ready. Some one passing the half-open door of his room heard a sound of snoring, and, looking in, saw Mr. W., with his book on his knee, slipped down in his chair, and apparently sound asleep. Dinner being ready, attempts were made to rouse him, but in vain. He was lifted to the bed, perfectly limp and lifeless. His face was ghastly pale, with a grayish tinge approaching cyanosis. His breathing was loudly stertorous, and his cheeks puffed out with expiration. The appearances were considered indicative of apoplexy by people of some experience who were present, and physicians were at once sent for in all directions. The first two physicians who arrived were on the point of administering a drop of croton oil, with the idea that the case was one of uræmia, when Dr. Lambert, the family physician, arrived. Dr. Lambert drew some of the urine, and, finding it normal, the croton oil was not given. Further examination proved that the pupils were normal, and that there was no evidence of paralysis or rigidity. The temperature was normal, and the heart and lungs seemed to be healthy. The stertor, coma, and a somewhat feeble and compressible pulse being the only symptoms noted, Dr. Lambert decided to wait for further developments before resorting to any heroic medication. After the coma had lasted two hours, the patient vomited a quantity of undigested food, which he had taken at lunch, and at once began to improve. His consciousness gradually returned, and a dazed condition, alternating with delirium, gradually took the place of coma. In his delirium he frequently referred to the lines which he had been reading at the moment when he became unconscious, and in his saner moments would start up and ask if dinner were not ready. Once, when his attendant was not quick enough to prevent him, he turned over in a dazed way, and fell from the bed to the floor. This seemed to rouse him, and five hours after his first attack his mind was clear again, although he felt weak. The next morning he felt perfectly well again, rose early, and went about as usual. He had never before experienced anything like this attack, and has enjoyed his usual good health ever since.

The striking points in this case are the profoundness of the coma, with cyanosis and stertor. The fact that the symptoms rapidly disappeared after a considerable quantity of undigested food had been vomited gives us a clue to the cause. By way of experiment, dogs have been abundantly fed and then obliged to exercise upon a treadmill; if the dogs be killed after four or five hours, the food is found undigested in the stomach. It is probable that Mr. W.'s digestion was in a similar way arrested by his continual rushing about and intense mental activity. The undigested food in his stomach, then, at length acted as it not infrequently

does in children, and induced coma by causing anæmia of the brain. This cerebral anæmia was doubtless epileptoid in character, and due to arterial spasm of reflex origin; it ceased as soon as the irritant was removed by vomiting, and consciousness then returned. Probably Mr. W.'s excitable nervous system rendered possible a train of phenomena seldom to be observed in adults.

CASE III.—An Englishman, aged forty, married, superintendent of a public institution. He had suffered from obscure ague at times; and, having suffered from headache and general malaise for some weeks last September, he began taking quinine without consulting a physician. For some months previously he had been very much overworked, and had occupied a position in which he was much harassed by numerous cares, so that he was at the time in a condition of physical depression. He had always been a hard-working business-man, and had never had any evidence of mental trouble of any kind. How much quinine he took he does not know; he took it, without measuring it, from a large phial full of the powder. After he had been taking quinine for several days in indefinite quantities, he began to imagine himself followed about the corridors of the institution by crowds of people who were whispering among themselves, or jeering at him, or at times merely watching his movements. This continued several days, during which he was supposed to be insane by the people about him, to whom he had communicated his hallucinations. At this time he was utterly unable to sleep. A rapid and permanent recovery followed seclusion, rest, sleep, and abstinence from quinine. It is now four months since the attack, and he has had no recurrence. He has always been a strictly temperate man, and had evidently not been drinking at the time of his mania.

This case occurred in the practice of Dr. G. L. Peabody, who has kindly contributed the foregoing history to this paper. The case is of great interest in showing that grave symptoms of insanity may develop without other apparent cause than physical depression from overwork; and that these symptoms may be completely dissipated when the patient has been afforded an opportunity to rest. In the present instance, a hurried and too positive diagnosis would have sent the patient to an asylum, lost him his situation, and damaged his prospects for ever.

AN ANENCEPHALIC MONSTER.*

By W. M. CHAMBERLAIN, M. D.

PHYSICIAN TO CHILDEN HOSPITAL.

This fetus was born at a premature twenty years of age, about six months advanced in pregnancy, on the 18th of March, 1882. In the second month of gestation she had a great night, followed by hysterical convulsions, at which the abdomen increased in size very rapidly. For the opportunity of presenting the specimen I am indebted to the kindness of Dr. T. H. Burchard, to whom it belongs.

The attending physician, Dr. Rae, of Jersey City, reports: "On arriving, I found the abdomen enormously distended,

* H. St. George was shown at the New York Ophthalmic Society, November 7, 1882.

pains recurring about once in five minutes, the os somewhat dilated and a bag of membranes protruding, which I ruptured; the feet then presented, and the fœtus was readily delivered. The placenta appeared to be normal."

This monster shows a well-formed skin, perfect nails, and a good deal of hair upon the limbs, which are of good shape and proportion. Its extreme length is twenty-four centimetres, and the circumference round the shoulders the same.

FIG. 1.

The weight is one pound five and a half ounces. When placed in an upright posture, the end of the nose is the highest point. Two well-formed nostrils open directly upward. The mouth is large, and, the intermaxillary bone being small, it assumes a triangular shape.

The head is retracted, and the anterior surface of the neck convex and extended. Above the superciliary ridges the two frontal bones are spread out like plates. The hairy scalp extends to within one centimetre of the iliac crests. Beneath this scalp and the integument of the back a dense fibrous layer like an aponeurosis covers in the posterior wall of the thorax. The external lamina is continuous with the pericranium. Between the laminae superiorly are the frontal bones, approximating their normal position and size, and below are the rudiments of the parietal bones flattened out upon the shoulders.

None of the vertebral arches are formed. The vertebral canal is covered by integument only, and contains only a trace of slimy matter. A probe passes through it into an

irregular cavity beneath the frontal bones. This cavity, being laid open, contains only some soft amorphous matter, and the structure of a large sac which had pushed its way to either side under the inferior and exterior angle of the parietal bones, and the remains now protrude in length about four centimetres in each post-axillary space.

FIG. 2.

The remains of these lateral sacs are so altered by long maceration that it is impossible to determine what the original shape may have been. They must have ruptured before birth. There must have been a large sac, apparently continuous with the cavity of the arachnoid. A residuum of fluid after evacuation, displaced by the breathing, which continued fifteen minutes after birth, distended the loculi of the sac, and suggested the idea that they might be a part of the organs of respiration.

The clavicles are present and well formed, but the sternum is wanting. The cavities of the thorax and abdomen were not opened.

The specimen, according to the classification of Geoffroy St.-Hilaire, which seems to be generally accepted, belongs to the order "*Anencephaliens*"; but neither the great work of Otto, nor the memoirs of the Museum of Natural History of Paris, nor the records of the London Obstetrical Society for seventeen years, figure or describe any such lateral exstrophy of the cerebral membranes.

Book Notices.

*Recent Works on the Opium Habit.**

Of the making of books upon narcotics and stimulants there is, apparently, no end; and the productions before us are rather examples of book-making than additions to scientific knowledge. Dr. Kane's opusculum contains, here and there, some attempts at accurate observation, but is largely built upon sensational clippings from newspapers and speculative estimates. We have an "estimated" Chinese population; an "estimated" percentage of Chinese who smoke an "estimated" amount of opium per diem; an "estimated" excess (through smuggling and otherwise) of consumption over import of opium, to the extent of about eight thousand pounds per annum; and a consequent estimate that there are about six thousand Americans addicted to opium-smoking. In opposition to the belief that opium is a preventive of malarial poisoning, Dr. Kane cites a case wherein "malarial symptoms of a well-marked type" are attributed to smoking this drug. The principal object of the book, however, is to point out how easily and speedily the vice of opium-smoking can be cured by the author's treatment, consisting in the use of capsicum, digitalis, and cannabis indica in large doses, often repeated; bromides of potassium and sodium in 100-grain doses twice daily; bi-muth and catechu in large doses; chloride of gold and sodium every two hours, with fluid extract of gelseminum; massage and electro-massage, with hot baths and cold spray; oxide of zinc and atropine for perspiration; hyoscyamus and chloral to produce sleep; afterward, jaborandi, chloride of ammonium and benzoic acid, nitrate of silver, tonics, phosphorus, and cod-liver oil. As this course is to be compressed into ten days, or, at most, a fortnight, it seems probable that the victim might emerge with little desire for opium or any other drug for some time to come. The author regards smoking as the least injurious way of using opium, and, in comparing its effects with those of alcohol, makes the somewhat startling assertion that the latter "enters directly into the composition of the tissues." The book concludes with the stereotyped denunciations of England's opium traffic, to the ruin "here and hereafter" of a nation of four hundred millions, among whom the number of opium-smokers is variously estimated at from one million to fifteen millions.

Mr. Moore's brochure, as its title implies, is an apology, not only for the Indo-Chinese opium traffic, but for the use of opium in moderation. From his point of view the abolition of the British opium trade would injure the Chinese themselves by obliging them to extend the culture and use of the native-grown drug, which he regards as more deleterious than the Indian product. He insists that the moderate use of opium, as of alcohol, is, under certain circumstances, even beneficial; that the proportion of those who abuse opium is no greater than that of spirit drunkards; and more than intimates that the introduction of opium has been largely instrumental in rescuing the Chinese from the excessive drinking which marked their earlier history. As prophylactic and curative in malarial regions; as enabling the moderate user to bear extraordinary mental or bodily fatigue, or

to subsist on scanty diet; as a nerve stimulant, especially suited to the constitution, habits, and pecuniary means of the Chinese, and preferable in all respects to alcohol—opium is lauded by the author, who further asserts that the Indian ryots are in no wise forced to cultivate the poppy, but would do so, even in opposition to law, for the sake of the profit arising from supplying the imperative Chinese demand for Indian opium; that the amount of Indian land devoted to such cultivation is too infinitesimally fractional to have any appreciable influence in the production of famine; and that the protests of the Chinese government have been dishonest, actuated chiefly by a fear of the exportation of silver, while it encourages the native cultivation of opium.

Of the third book on our list, the less said, perhaps, the better. In a turgid style the author describes his peculiar philosophy touching various drug habits, with incidental lucubrations on consumption, dyspepsia, uterine disease, tapo-worm, parturition, and other topics. In "cases of phthisis," to facilitate the removal of the "infiltration" which is "accumulating in the alveole," he insufflates the following powder: "℞ Argentia nitras, gr. ij; pulvis Peruvia, ʒj. M. Triturate for ten minutes"—a prescription which, like most of his recipes, would infallibly choke any stickler for latinity. Chlorinated lime is advocated to produce "stuffing" of cancerous tumors; in sciatica, "podophyllin is indicated, with an anemia to clear out the lower bowels"; venesection and "claterian" are among his resources in acute alcoholism; painless parturition is said to be secured by keeping the pregnant woman upon "a fruit diet," particularly avoiding wheat-flour or other articles containing earthy or calcareous matter which "goes to supply the brittle, unyielding element in bone"—such abstinence rendering "the framework of the fetus yielding and pliable, enabling it to glide through the pelvis easily." (The author omits to inform us of his method of treating rickets.) Bromide of potassium is unqualifiedly condemned on the syllogistic ground that, since it is largely given to epileptics, and since masturbation is frequently practiced by such patients, ergo its use leaves its victims "pre-disposed to acquire vile and degrading habits." Holding that total abstinence is the only safeguard for the coming man, the writer would have every youth at the age of fourteen put under a deterrent dietetic course wherein "every particle of food must be thoroughly impregnated" with the following mixture: "Whiskey, ʒ ij; sherry wine, ʒ j; port wine, ʒ j; lager beer, ʒ j; gin, ʒ ij; cider, ʒ j; rum, ʒ j; champagne, ʒ j." This menu is to be continued for a week or ten days after nausea and persistent vomiting shall be induced, bearing in mind that "a human being can go for from fifteen to twenty-five days without food of any kind"—until, in fact, the patients "so abhor the taste and smell of liquors as to resign themselves to the horrors of starvation rather than endure the taste." It is assured that forever thereafter they will remain compulsory teetotallers. Altogether, Dr. Hubbard's remarkable treatise impresses us as one eminently calculated to serve as a text for the benches of the American Academy of Medicine.

A Practical Treatise on the Diseases of the Uterus, Ovaries, and Fallopian Tubes. By A. COURT, Professor of Clinical Surgery, Montpellier, France. Translated from the third edition by his pupil, AGNES M'LAREN, M. D., M. K. Q. C. P. I. With a Preface by J. MATTHEWS DUSCAN, M. D., LL. D., F. R. S. E., Obstetric Physician to St. Bartholomew's Hospital, London. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. viii-810. [Price, cloth, \$6; sheep, \$7.]

A work like this of COURT's, which, in the original, has been favorably known to the profession for a number of years and has reached its third edition, does not call for an analytical

* "Opium-Smoking in America and China. A Study of its Prevalence and Effects, Immediate and Remote, on the Individual and the Nation." By H. H. KANE, M. D., etc. New York: G. P. Putnam's Sons, 1882. Pp. xiii-156. [Price, \$1.]

"The Other Side of the Opium Question." By W. J. MOORE, L. R. C. P. Edin., M. R. C. S. Eng., L. S. A. Lond., etc. London: J. & A. Churchill, 1882. Pp. 95. [Price, 2s. 6d.]

"The Opium Habit and Alcoholism," etc. By Dr. FRED. HEMAN HUBBARD. New York: A. S. Barnes & Co. Pp. viii-229.

survey of its subject-matter at the hands of the reviewer when it appears in translation. The merits of the book are well known, and, of course, we find in the English version the same characteristics of full and faithful treatment of all the details of the different subjects, the same profuse illustration, the same lucid exposition of the French view of those branches of gynecology of which it treats. We are informed in the preface, by Dr. Duncan, that certain chapters of the third French edition were abridged by the author prior to the making of this translation, but no indication is given as to the portions so modified, nor does it appear that the translator has introduced any notes or original matter of her own—a rather unusual instance of modesty. If, then, we turn our attention to the work of the translator, considered apart from that of the author, it must receive high praise for the smoothness of its English, and for the success with which French idiomatic expressions and mere verbal transiteration are avoided. We have, in short, a good, readable English version, in which but few blemishes are to be noted. Exception may indeed be taken to the use of the word “modifier,” on page 210 and elsewhere, to signify *alterative*, and to “Canquoin” for what is commonly known as *Canquoin's paste*. Weights and measures are commonly given according to the English notation, though occasionally the metric has been allowed to stand. A more detailed index would greatly facilitate reference to a book which is likely to be much used for that purpose, and this deficiency is not made good by fullness in the table of contents. Looked at, however, from the American point of view of to-day, the most striking defect of the book is the absence of any allusion to laceration of the cervix uteri as a pathological condition, as standing in an etiological relation to well-known symptoms, or as a subject of treatment. It is hardly conceivable that the teachings of Emmet are unknown to the professor at Montpellier, and it is hard to understand how so competent a translator could have refrained from adding a note on this important topic. Yet we find the author hovering over the very point, in his remarks on “hypertrophy of the cervix limited to one segment or one lip,” without touching it, and on page 636 there is an illustration, credited to Virchow, of “indurated acne of the cervix,” which presents an almost typical picture of a deep laceration and eversion of that organ.

The Concepts and Theories of Modern Physics. By J. B. STALLO. New York: D. Appleton & Co., 1882. Pp. 308. [International Scientific Series.]

INASMUCH as the series to which this book belongs is designed for the non-expert as well as for the expert, we may venture to interpret the impression which it may give to the former. The author says in his preface that his is not to furnish a new theory of the universe, but that the work is designed as a contribution to the theory of recognition. He conceives that the metaphysical spirit has prevented the just apprehension of the truths of science, and this statement is elaborated in the tenth, eleventh, and twelfth chapters. Metaphysics considers the *summa genera* of abstraction, the highest concepts as the *most*, and the data of sensible experience as the *least* real of all forms of existence. It starts with the subject-object and reasons to the object-object, while modern physical science seeks to rid itself of this fallacious method, and to reason only from sensible experience, with a success which is only partial. In seeking to advance this attempt the author finds it necessary to restate many propositions. Starting with the science of mechanics as the basis of all force, he proceeds to discuss the fundamental hypotheses of chemistry, physics, astronomy, and, indeed, of mathematics, pure and applied, and the bearing upon science of

the most noted systems of philosophy. The chapter on modern transcendental geometry is fairly interesting, bringing out the views of Riemann and Helmholtz concerning a fourth dimension, etc., which, if true, will involve a reconstruction of the existing ideas of sense-perception. The style of the author is not always clear, but we admit that the fault may be due partly to the obscurity of the subject.

As to what the author's theory of the universe is he does not give us a hint. In his first discussions he conveys the impression that he will eventually pin his faith to the atomo-mechanical theory. This impression is entirely destroyed when, in the closing chapter of the book, he summarizes concerning it by affirming that it neither accounts for the phenomena of organic life nor explains the ordinary cases of inorganic physical action. The atomic theory of matter, the mechanical theory of the origin of the universe, and the nebular hypothesis are all proved to be unsatisfactory and fallacious. The book is made up of negations, and reminds one of a man setting up ten-pins only to knock them down. What the author's theory of cognition is the reader is left to conjecture, and it is possible that he will rise from the perusal of the book with a most unsatisfied feeling, excepting that he has finished the task. He will be compelled, however, to admire and respect the great acquirements of the author, which have enabled him to toil in the most varied fields of science, and to go to original sources in several languages and study the most profound and abstruse problems which the human mind is capable of proposing.

Rheumatism, Gout, and Allied Disorders. By MORRIS LONGSTRETH, M. D., one of the Attending Physicians of the Pennsylvania Hospital, etc. New York: William Wood & Co., 1882. Pp. vii-280. [Wood's Library of Standard Medical Authors.]

WE hoped to find in this book either something new upon the subject, or an improved restatement of what had already been written. Our hopes have not been altogether realized. The author has evidently had experience, and has been a good observer, but as a result he can only say: “The position which rheumatism now occupies is that of a group of symptoms, having a common cause, not necessarily connected, without any discovered anatomical basis.” More thorough examination of the blood of rheumatic persons, he suggests, may lead to more accurate knowledge of this disease. As to its origin, cold is about the only cause to which we can definitely point, the lactic-acid theory, the inflammatory theory, and others being insufficient. We think that the vaso-motor theory will bear further study. From what is known of the action of heat and cold upon the vessels near the surface, we can deduce still more, and it may lead to the solving of the vexatious question as to the cause of the inflammation in the joints.

The clinical pictures and the morbid anatomy constitute by far the best parts of the book, evincing matured experience, sufficient investigation into collateral literature, and familiarity with the evidence which is to be obtained in the section-room. As to treatment, the author quotes Garrod in favor of the quinine-alkaline treatment. The use of salicin and its compounds has also been highly satisfactory in his hands.

Gout is discussed in a chapter containing only twenty-six pages, two hundred and fifty having been allotted to rheumatism. The “allied disorders” are not referred to at all, and we can only infer that the author considers this subject sufficiently elucidated in his remarks concerning the complications and concurrent phenomena of rheumatism. The chapter upon gout adds nothing to what Garrod taught years ago, and for this reason its brevity is to be commended.

THE NEW YORK MEDICAL JOURNAL.

A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 27, 1883.

THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE.

THE third volume of the "Index-Catalogue of the Library of the Surgeon-General's Office, United States Army," embracing the entries *cholecyanin* to *Deondi*, excites, first of all, like the preceding volumes, a feeling of admiration for the industry, accuracy, and well-ordered system with which Surgeon Billings and his collaborators are working at the task which they imposed upon themselves. We have before alluded to the surpassing value of the "Index-Catalogue" to our profession, and, as a natural consequence, to the community in general—a value that must be more and more widely appreciated with the appearance of the successive volumes. We understand that the fourth volume is now going through the press, and that during the present session Congress will be asked to grant an appropriation for the printing of the fifth volume. We can not entertain the thought that the national Legislature will hesitate to accede to this request. Any hindrance to the publication of the consecutive volumes of this great work would not only prove a grievous disappointment to those whose labors in the advancement of medicine are dependent in great measure upon this means of rendering its literature available to them, but it would retard the progress of the nation by just so much as American physicians would find themselves hampered in the effort to keep pace with what is being achieved elsewhere. No country can afford to refuse any reasonable aid to the improvement of a department of knowledge so intimately connected with the national well-being as that of medicine.

Besides the "Index-Catalogue," the "Medical and Surgical History of the War of the Rebellion," of which it is expected that the third surgical volume will be laid before Congress during the present session, is a work that not only adds luster to the medical corps of the army, as well as to their temporary coaljutors drawn from civil life during the late war, but is also helping most powerfully to raise military medicine to a higher plane of efficiency than it has ever attained to before. We are under the impression that the Homeric dictum,

"A wise physician, skilled our wounds to heal,
Is more than armies to the common weal,"

has never been questioned. Of how much more importance, then, is it for a nation to provide every possible means to enable a generation of physicians—men from whom its army medical corps must be recruited from time to time—to begin where their predecessors left off, rather than waste the better portion of their energies in reaching what might have been their point of departure. The country, therefore, can not allow either of these two great works to be delayed or crippled in its completion.

The consideration of these literary undertakings naturally

leads us to reflect upon an institution that is not only the pabulum of one of them, and, to a certain extent, the nursery of the other, but also, in a way quite independent of either, a factor of the first importance among the sources of the future achievements that may be expected of medicine in this country. We refer to the library of the Surgeon-General's office, containing nearly sixty thousand volumes and more than that number of pamphlets—all on medicine and its branches. It is said there is a scheme on foot to deprive the library of this special and independent character by making it part and parcel of the Library of Congress. We can not see that any advantage would accrue to the public interest by such a consolidation. On the contrary, it does seem that, removed from the charge of those who have made it what it is, ingulfed in a huge mass of general literature, and placed where systematic readers would be repelled rather than attracted, the library of the Surgeon-General's office would be shorn of much of its present usefulness.

The building in which the library is now stored is indeed inadequate to the purpose, and not well adapted to the safe-keeping of the treasures it holds; and it is true that the library of Congress stands some chance of soon being provided with an ample fire-proof building. These considerations, however, do not seem to us to constitute a good reason for the absorption of the lesser by the greater collection. No library is absolutely assured against accidents; it is well, then, not to consolidate elements so diverse as a general and a special library, but rather to consult both utility and prudence by keeping them apart. Yet, by all means the library of the Surgeon-General's office should be suitably housed. A building to accommodate both the library and the Army Medical Museum, as suggested in a recent report by the Surgeon-General, it seems to us incumbent on Congress to provide for. We have reason to think that this is the general wish of the profession, and certainly, since the library owes much of its magnitude to contributions from physicians in civil life, that wish has a solid claim to consideration.

MEDICAL ETHICS IN NEW ORLEANS.

WE have been much interested by an address recently delivered before the New Orleans Medical and Surgical Association, on the occasion of its ninth anniversary, by the outgoing President, Dr. Joseph Holt. We beg to thank the author for a copy of the address, in pamphlet form, reprinted from the "New Orleans Medical and Surgical Journal."

It seems that, although the association is but nine years old, and although it was contemptuously prophesied at the outset that it would collapse within six months, it has not only had a creditable career as regards the ordinary work of medical societies, but has also exerted a powerful influence in bringing the members of the profession in New Orleans into a state of harmony and mutual esteem. In short, it has become a power, and its energy has been exerted for the common good.

We infer that the relations of New Orleans physicians to each other were about as dissatisfying as they could be at the time the association was organized. Previous attempts to establish medical societies had failed to result in any lasting organi-

zation, but, dying like noxious weeds, had, to follow Dr. Holt's diction, left behind them baneful seeds that sprouted and grew and brought forth fruits—hatreds, criminations and recriminations, backbiting, quarreling, strife, and all manner of uncharitableness. Even casual conversation, he adds, was burdened with the recital of some injurious story or severe criticism of another. With few exceptions, physicians avoided each other with suspicion and contempt. As for the societies that had been started, very little was done by them in the way of worthy papers or searching discussion on any subject in medicine or the collateral sciences. Such matters were considered irrelevant; the members "asked no odds of science," but busied themselves with ethics. They wrestled with ethics, and were thrown at every round.

Such was the state of things when a few of the younger men, not yet hopelessly saturated with prejudice, began the gloomy undertaking of bringing order out of chaos. "A sense of unseen danger," says Dr. Holt, "compelled the inquiry—What is the stone of stumbling and rock of offense upon which these associations have wrecked themselves? Too much legislation. What was the cause of death? They were drowned in too much law. Why does it delight medical men to legislate and create much law? Because they, like their ecclesiastical brethren, are conservative and behind the democratic spirit of the age. They love to exercise authority one over another, and hallow the precepts and examples of their predecessors, back to the darker ages, and so venerate and adhere to the methods of discipline through '*the medicinal pain*.'" But those young men succeeded in their undertaking, and their success was due, as we deduce from Dr. Holt's statements, to their letting ethics alone.

We regret that the space at our disposal will not allow us to follow Dr. Holt's vigorous portrayal further; but we have said enough to show its purport. So far as we can judge, Dr. Holt has given a truthful picture of the matters with which he deals, and we infer that for the past nine years New Orleans has been practically without a code of medical ethics; and yet the association that brought this state of things to pass is the only one that has achieved an assured position in that city. If in any way the interests of the New Orleans profession have been injured by the change, it would be well to have the fact made known, that their brethren throughout the country may view their experience in the light of all the information that can be brought to bear on it.

THE NEW PHARMACOPEIA.

III.

THERE are some omissions that seem to us noteworthy. We do not refer to drugs and preparations dropped from the list, but to matter which might have been given with advantage, we think, with the list as it stands. In the item of synonyms, the committee were justified in declining to give them *in extenso*, but in some instances they seem to have erred in the other direction. We would note the following examples: In addition to chloride of ammonium, the term *muriate of ammonia*, being

very commonly employed, would be of assistance to many who have not yet familiarized themselves with modern nomenclature; and, for the same reason, it would have been well to give *podophyllin* as a synonym of resin of *podophyllum*. In a number of instances a service has been rendered the reader by specifying the nature of a given salt—whether, for instance, the salt is ferrous or ferric, and the like. We should have been glad to see this information given in all cases. The English equivalent of *saccharum* is given simply as sugar. Cane-sugar is undoubtedly meant, and we think it should have been so stated. Sulphate of cinchonidine is described as "the neutral sulphate of an alkaloid prepared from certain species of cinchona," etc.—*which* alkaloid, is not specified. Of course, it is quite obvious which one is meant; the point is, that the alkaloid itself is not described, but only its sulphate. Heavy magnesia is amply designated by the title *magnesia ponderosa*, but light magnesia is called simply *magnesia*.

We think an error has been committed in not giving processes for the manufacture of drugs in all instances. To be sure, it is only in regard to preparations that are seldom if ever made by the apothecary that these processes have been omitted, but we think those who buy the book are entitled to just such information as would have been supplied by their insertion. Moreover, we can conceive of circumstances under which it would be highly desirable for an apothecary to make an alkaloid, for example. As matters stand now, so important a remedial agent as aconitine is not official—simply, we infer, because such various substances figure under that name in the market, and because our knowledge of what relates to the best mode or modes of making aconitine is exceedingly vague and unsatisfactory. Now, it could not reasonably be expected of the committee that they should turn this chaos into order, but the question¹ arises whether they would not have done well to specify some one of the various substances that pass under the name of aconitine, as a provisional adjustment of the matter, pending the next decennial revision. Certain it is that the profession will go on using so-called aconitine, and we fear it is inevitable that any future summary of the experience that may be recorded with the article will be sadly lacking in definiteness, owing to the uncertainty as to what the putative aconitine really was in the various instances involved—an uncertainty that might have been done away with in a measure by making some one of the aconitines in the market official.

THE NEW YORK ACADEMY OF MEDICINE.—At a recent meeting of the Academy the following officers were elected: President, Dr. Fordyce Barker; Vice-President, Dr. Horace P. Farnham; Secretary, Dr. W. H. Katzenbach; Corresponding Secretary, Dr. John G. Adams; Treasurer, Dr. W. F. Cushman. Dr. Gouverneur M. Smith was elected a Trustee; Dr. Charles Wright, Treasurer of the Board of Trustees; Dr. E. L. Partridge, a member of the Committee on Admissions; Dr. H. E. Crampton, to the Committee on Ethics; Dr. John C. Dalton, to the Committee on Education; and Dr. A. McLane Hamilton, to the Library Committee.

DR. J. BERDON SANDERSON has been made Waynflete Professor of Physiology in the University of Oxford.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

A STATED meeting was held December 12, 1882. Dr. T. M. MARKEE, President, in the chair.

EMPHYEMA; PERFORATION OF THE BRONCHI AND THE DIAPHRAGM; RECOVERY.—Dr. F. LANGE presented a male patient, nineteen years of age, with the following history: He was a healthy member of a healthy family, and a student. After repeated attacks of gastric disturbance, in the summer of 1881, he was taken, September 2d of that year, with severe gastro-intestinal catarrh, which became so obstinate that he was confined to the bed from the eighth to the fifteenth of that month, when he was under the care of Dr. Henkel. He had only a moderate fever, but gradually lost flesh and strength. Very soon after this, a deep-seated abscess developed on the inner aspect of the arm, and it seemed to take its origin in the muscular substance of the biceps. Dr. Lange opened the abscess in the presence of Dr. Henkel on the 26th of September, and the wound healed without further trouble, but the patient did not rally entirely. On the 7th of October he was taken quite suddenly with so severe pain in the lower part of the thorax, in the right side, and went to bed again. Very soon afterward the physical signs of pleuritic effusion became apparent, and, in a comparatively short time, the level of the fluid was as high as the middle of the scapula. The presence of crepitus and near bronchial breathing above the line of dullness made it probable that the inflammatory process, to some extent, affected the lung tissue. The area of dullness was considerably smaller in the axillary region than behind, and was almost absent in front. There was continued fever, with exacerbations at night, and the patient had no appetite and lost flesh and strength rapidly. On the night of the 19th of October perforation of the bronchi occurred, and large quantities of pus were expectorated. On the following day the patient felt much relieved, although he was quite exhausted. Dr. Henkel then found the physical signs of pyo-pneumo-thorax, especially the metallic sounds. The patient did not rally as had been expected, the fever did not cease, and the debility increased. It was impossible to make a thorough examination of the chest, on account of the extreme weakness of the patient, but it was ascertained that the respiratory murmur could be heard from above downward to the fourth intercostal space in front, and to the middle of the scapula behind. At the latter point the breathing was amphoric in character. The level of the fluid was considerably lower down. Succussion sound could be obtained distinctly. Dr. Lange saw the patient again in consultation on the 23d of October, and, from the history of the case, felt certain that there was pus in the pleural cavity, but aspiration gave a negative result. Puncture was made at four different places, but only a few drops of blood mixed with air were obtained. Assuming that the collection of pus might be near the center of the lung, deep punctures were made. Dr. Lange had already determined to desist from further surgical interference when he discovered, at the lowest part of the thorax, toward the lumbar region, and against the lateral border of the sacro-lumbalis, air under his fingers on pressure upon the deep tissues. He punctured at that point, found pus, and then opened the cavity by a free incision. There was an abscess below the diaphragm, along the under surface of which the finger could be passed after being introduced through the incision. Apparently the empyema had perforated the diaphragm. The expectoration very soon ceased, and the patient made a rapid recovery. With the exception of slight retraction of the lower and front part of the right side of

the chest, with diminished respiratory murmur in that region, there was scarcely any difference to be noticed when the two sides were compared. Dr. Lange thought that the point at which perforation of the diaphragm occurred was possibly at the gap between the vertebral and costal part of that muscle, which is sometimes very large. He was unable to make out whether the abscess was intra- or extra-peritoneal, but thought it was probably the latter. The kidney, on account of swelling and infiltration of tissues around it, could not be felt distinctly. The outline of the liver was recognizable by palpation.

Last summer Dr. Lange was shown, at Professor Thiersch's clinic, in Leipzig, a patient who had sought admission because of a freely discharging fistula over the anterior aspect of the right femur. The etiology of the abscess became apparent when purulent expectoration began simultaneously with the cessation of discharge of pus from the fistula. The patient stated that this had occurred several times, and examination of the chest revealed upon the right side some evidence of an encapsulated empyema, for which thoracocentesis, with resection of a rib, was performed. Recovery followed rapidly. Dr. Lange was inclined to believe, although unable to prove it, that there was a causal relation between the abscess in the biceps and the empyema, the latter being the result of an embolic process.

In reply to a question, he stated that the largest collection of pus was above the diaphragm; probably a pint being in the cavity below it.

The President remarked that in a similar case he found the accumulation of pus much larger below than above the diaphragm, pressing into and upon the abdominal cavity.

Dr. ALFRED C. POST asked which occurred most frequently, abscess originating in the thoracic cavity, with perforation downward, or abscess beginning in or near the liver, with perforation upward.

Dr. CHARLES K. BRIDGON replied that he thought perforation upward occurred most frequently. In a similar case admitted to the Presbyterian Hospital, probably a year ago, the cavity of the chest had been aspirated and a large quantity of pus removed. There was dullness on percussion up to the spine of the scapula behind and to a line nearly upon the same level in the axillary region, and there was a large area of dullness in front. There was also a marked bulging in the neighborhood of the liver, which was mapped out quite accurately—the area occupied by an enlarged liver. Fluctuation was detected by palpation over this large swelling, and the sensation could be distinctly felt carried through to the lumbar region. Dr. McBride, one of the visiting physicians, examined the patient, and regarded it as a case of perinephritic abscess which had pressed the diaphragm upward, developing a condition simulating empyema. Dr. Bridgon attempted to aspirate from behind, and passed the needle three or four inches deep without obtaining anything. He then aspirated in front and removed a large quantity of bloody serum. There was no appearance to the naked eye of pus in the fluid, but the microscope revealed a certain number of pus corpuscles. He aspirated several times subsequently, and obtained the same kind of fluid, but never at any time fluid which had the usual appearance of pus. The patient subsequently came under the care of Dr. L. A. Stimson, who made an incision behind into the cavity of the chest and gave exit to a large quantity of pus. The patient subsequently expectorated large quantities of pus, and it was noticed that when the expectoration was obstructed, or deficient in quantity, the sub-diaphragmatic swelling increased in size. At the time he had some doubts as to whether the abscess was sub-diaphragmatic or not.

Dr. LUNN M. YARR asked an item in the clinical history which filled up an interspace between the service of Dr. Brid-

don and that of Dr. Stimson. He saw the patient soon after Dr. Briddon first saw him. The man came into the hospital one afternoon greatly oppressed in breathing, and Dr. Yale aspirated his thorax and drew away a little more than ten pints of pus. This was followed by the operation already alluded to, and performed by Dr. Stimson. As he recollected, Dr. Stimson was not quite sure where the cavity was, even after the operation had been performed. Dr. Yale thought, however, the opinion of the majority of the visiting surgeons was that the case was one of perinephritic abscess which had worked its way upward.

Dr. LANGE then read a paper entitled *ANATOMICAL AND CLINICAL CONSIDERATIONS CONCERNING THE RETRO-PERITONEAL SPACE IN THE REGION OF THE LAST RIB*.

Dr. W. S. HALSTED asked Dr. Lange if he believed that the lower limit of the pleural cavity was lower than that which had been given by Dr. Hull.

Dr. LANGE replied that in some cases it was much lower, and in other cases it was higher. On the average, however, he should say that it was lower.

Dr. ROBERT F. WEIR remarked that it was not often we had the opportunity of testing upon the living subject the accuracy of the remarks made by Dr. Lange. Recently, however, he had had the opportunity of cutting down upon the tissues in that region which were tolerably normal. The operation was one for making fast or anchoring a movable kidney. In that instance he found that the kidney fat, in a patient only moderately stout, was, on being incised or torn through, capable of being readily separated, and in that manner enabling him to expose the kidney, and by traction on this investing tissue to raise the organ toward the surface quite satisfactorily. However, even in this case of movable kidney there was considerable difficulty in reaching and appreciating the pelvis of the organ. He put his finger in for the purpose of education, because one or two years ago he had placed upon record the view that in those cases in which there had been for years previous signs of obstruction of one ureter, and then signs of obstruction in the other ureter developed, one might proceed to a lumbar incision, and open the pelvis of the kidney or the ureter above the site of obstruction with a view to saving the patient's life, an operation which had recently, he had read, been performed by Bardenheer with success.

Dr. LANGE remarked that the position of the kidney could be changed considerably in a lateral direction. He had also found that if the lower part of the kidney was pulled upward and laterally, the entire organ would be pulled not only laterally, but at the same time its lower edge would be turned upward and made to perform a sort of torsion.

Dr. BRIDGON asked Dr. Lange what incision he would make in nephrectomy.

Dr. LANGE replied that he would make an incision extending from the apex of the last rib if that could be felt; in other words, make Czerny's incision. If the rib could not be felt, he would take the line of the sacro-lumbalis, or the quadratus lumborum muscle. In reply to a question by Dr. Halsted, he remarked that counting from the spines could hardly be depended upon as giving proper directions for making the incision.

VESICAL CALCULUS.—Dr. H. B. SANDS presented five small vesical calculi, the largest being one half of an inch, and the smallest about one third of an inch in diameter, which he had removed thirteen days previously by lateral lithotomy. The interest of the case consisted in the fact that this operation had to be performed in the place of the crushing operation, which would have naturally been selected for the removal of stones of this size. The patient was a man fifty-seven years of age, who had suffered from symptoms of stone for three years. He was seen by Dr. Van Buren between two and three years ago, when

it was discovered that his prostate gland was unusually large. On that occasion a sound was introduced into the bladder, but a stone was not detected. Some doubt seemed to have been felt by Dr. Van Buren as to whether or not a stone was present, for he told the patient that he wished him to return for another examination. Considerable irritation following this exploration, the patient did not return to have it repeated. He continued to suffer more or less from cystitis and irritable bladder, and, about two months previous to the time when Dr. Sands first saw him, his symptoms became very severe. The patient suffered from spasmodic contraction of the bladder, accompanied with great pain. Owing to prostatic hypertrophy, he had for nearly two months been unable to evacuate the bladder except by means of a catheter, which, however, was readily introduced. Previous to Dr. Sands's visit the patient had been seen by Dr. Doughty, who had sounded him upon three occasions. At the first examination a calculus was detected, but it was observed that the sound, a Thompson's searcher, could not be moved as freely as usual in the bladder. The second and third examinations failed to detect any stone. When Dr. Sands visited the patient he administered ether, and made a careful exploration of the bladder and rectum. An instrument with a large curve passed readily into the bladder, but one having the curve of Thompson's sound could not be made to enter. This fact had been previously noticed by Dr. Doughty. The prostate, when examined by the rectum, was found to be exceedingly large. The urethra was measured, and was ascertained to be nine and a half or ten inches in length. When the Thompson's searcher was introduced it would pass the entire length of the instrument, which was nine and a half inches, and still its point did not enter the bladder. The instrument seemed to be arrested by some bar of prostatic tissue. Introducing the instrument as far as it would go, Dr. Sands endeavored to move it, but the point remained nearly stationary, apparently grating against a rough surface of prostatic tissue. A stone was detected, situated upon the patient's left side, and apparently just at the neck of the bladder. Dr. Sands decided to perform lateral lithotomy, and thirteen days ago he removed the five calculi presented; four were whole, and the fifth one was in fragments. Each calculus consisted of a uric-acid nucleus, covered with concentric layers of phosphates. The patient, a few hours after the operation, had a chill, and began to suffer from retention of urine. Dr. J. C. Hutchison, who had assisted at the operation, was called, and succeeded in introducing an instrument into the bladder through the penis; using this as a guide, he introduced a Nélaton's catheter through the perineal wound into the bladder, and tied it in position. This gave the patient complete relief; and, through the instrument remaining in the wound, the urine was allowed to trickle for eleven days. About two days after the catheter was introduced it was noticed that the point of the instrument tended to escape from the bladder into the deeper part of the urethra. Believing that it would be better to let the instrument lie thus in the wound than in the bladder, thus preventing the liability to incrustation, it was allowed to do so, and every two or three hours it was introduced far enough to allow the urine to escape. Two days ago the catheter was removed from the wound, and has since been introduced through the penis whenever necessary.

Dr. Sands regarded the case as interesting in two respects. In the first place, it afforded an illustration of the fact that, even when the stone was small, all cases of vesical calculi could not be treated by the crushing operation. A similar case came under his observation about six weeks ago, in which he was obliged to perform lithotomy and remove a stone not larger than an almond, because he failed, after repeated attempts, to seize the calculus with the lithotrite. In this case there was no

difficulty in inserting the instrument into the bladder, but it could not be made to seize the stone, which lay in a pouch behind the prostate. This cavity, which was apparently bounded behind by a muscular band extending between the orifices of the ureters, formed a cavity which was not more than one inch in its longest diameter, large enough to contain a stone, but not large enough to allow the blades of the lithotrite to open and seize it.

The second point of interest was the occurrence of retention after the operation of lateral lithotomy in which a pretty free incision was made. This was the second case in which this rare complication had followed lateral lithotomy in his practice. Usually the urine flows freely from the wound, and catheterism is not necessary. In the other case, as in this, the prostate gland was considerably enlarged, and he inferred from his experience that when lateral lithotomy is performed under such circumstances, especially where the bladder is weak, the proper course would be, after extraction of the stone, to wash out the bladder, insert a flexible catheter, and allow it to remain in position. In addition, he believed it to be advisable to allow the point of the instrument to recede from within the bladder, and subsequently to push it forward at regular intervals to permit the escape of the urine.

Dr. Post referred to a case in which he assisted the late Dr. Buck in the performance of lateral lithotomy, and retention followed the operation. On introducing the catheter the next day, a large quantity of urine was drawn off. In that instance a fatal result occurred. There had not been retention before the operation.

Dr. Weir referred to a case in which Dr. Buck operated, and in which retention followed the operation; but in that instance another calculus was found in the bladder.

Dr. Post remarked that Mr. Liston, of Edinburgh, once remarked to him that he was in the habit of introducing a catheter and allowing it to remain after performing lithotomy, because he believed that the safety of the patient was promoted by it.

PTOSIS WITHOUT STRABISMUS, AND AMAUROSIS WITHOUT A DILATED OR SENSITIVE PUPIL.—Dr. Post narrated a case as follows: A boy, fifteen years of age, was brought to his clinic last Saturday who had been in the enjoyment of fair health, except that he had suffered from headache during the last two years to a considerable extent. About five days before he was brought to Dr. Post the patient was suddenly attacked with ptosis of one eye, and there was almost absolute loss of vision attending it. There was bare perception of light. There was no strabismus; the pupils of the two eyes corresponded with each other, and both were sensitive to light. The occurrence of ptosis without strabismus, and amaurosis without dilatation or sensitiveness of the pupil, seemed to him to be unusual.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held November 7, 1882, Dr. C. C. LEE, President, in the chair.

RECURRENT FIBROID TUMOR OF THE ABDOMINAL WALLS.—Dr. H. T. HANKS presented a fibroid tumor, which was the second one that he had removed from the abdominal wall of the same patient within three years, and a third one had been removed by another physician. The first tumor was situated between the internal oblique and the transversalis muscles, on the right side, near Poupart's ligament, while the last one was situated in the transversalis muscle, on the left side, near the umbilicus, and had more of the characteristics of malignant disease. The following was the report of the microscopical examination made by Dr. W. H. Welch:

The specimen was hardened in absolute alcohol, and showed, on microscopical examination, the following condition: A dense fibrous base, supporting numbers of spindle cells in spots, and groups of round cells were seen. There were places where the prominence of the spindle cells suggested sarcoma. The tumor, both from its clinical history and from its essential structure, may be classified among so-called recurrent fibroids.

The PRESIDENT remarked that a recurrence of fibroid tumors in muscular tissue was very exceptional, this being the only case of the kind which he had seen.

ACRANIAL MONSTER.—Dr. W. M. CHAMBERLAIN presented the specimen, and subsequently wrote out the history. [See p. 93.]

VESICAL CALCULUS WITH A HAIR-PIN NUCLEUS.—The specimen was presented by Dr. W. R. GILLETTE, who had removed it from a German girl nineteen years of age, at St. Francis's Hospital. Her symptoms were emaciation and incontinence of urine. The stone, with the hair-pin nucleus, was removed through the vesico-vaginal septum. The patient professed to have no knowledge of how the hair-pin had entered the bladder. Dr. Gillette also presented another specimen, with a similar history, which was removed from a patient at Charity Hospital some years ago. — Dr. GARRIGUES and Dr. HANKS each mentioned a similar case.

The PRESIDENT had seen a calculus, removed from a man at Bellevue Hospital some years ago, by Dr. Van Buren, which had for a nucleus a head of wheat that the patient had introduced partially into the urethra and was afterward unable to extract. Some years ago he presented to the Pathological Society two specimens of stone in the female bladder, which had for a nucleus the handle of a spoon. One he had removed himself; the other was removed by another surgeon.

Dr. B. F. DAWSON remarked that in the Army Museum at Washington there were pieces of brick which had been removed from the bladder of a negress.

PROBABLE TUBAL PREGNANCY.—Dr. HANKS had been called in consultation by Dr. Bradshaw to see a multipara who should have menstruated on the 16th of October, and who very soon afterward felt pain in the region of the left ovary. When he saw her, which was about the 1st of November, she was losing considerable blood. He ordered ergot and opium, and directed the vagina to be tamponed. Afterward, on removing the tampon, a very small ovum, with the membranes, was discovered in the blood which had been discharged. The depth of the uterus in the direction of the right ovary was about three inches, while in the direction of the left ovary the depth was four and a half inches, which would seem to indicate tubal pregnancy on the left side.

The PRESIDENT remarked that this case suggested a point of practical importance. He had recently been called in consultation to see a multipara who had aborted at about the second month, and it was supposed that a part of the placenta remained in the uterus. He found, on examination, that the appearance which had led to this supposition was due to a softened and lacerated condition of the cervix, and the presence of exuberant granulations. Doubtless this condition sometimes led the physician to adopt unnecessary and harmful measures for the removal of the placenta in cases of abortion in the early months of pregnancy.

HYSTERIC DYSM.—Dr. RALPH M. E. EMMETT presented a case as follows: The patient first came to the Woman's Hospital five years ago, suffering from proclivencia of the uterus, which was partially relieved by certain plastic operations on the vagina. Last spring Dr. Emmet performed Le Fort's operation, which proved successful; but some months afterward the patient gave way to a fit of anger, and the uterus, which contained a large

fibroid tumor, was again crowded down toward the vulva. The patient was suffering greatly from pain, and desired to have the tumor removed. Dr. Emmet performed the operation on Friday last, removing the body of the uterus with a portion of the cervix, the ovaries, and the tubes. The mass was composed of eight fibroids, mostly intramural. In order to avoid hemorrhage, Dr. Emmet made use of a plan first introduced, he believed, by Olshausen, but since constantly practiced in England, viz., that of encircling the whole mass at its base by a long piece of Esmarch's tubing prior to its amputation. This tubing, being put about the tumor at full tension, was grasped at the point of crossing of the two extremities by a strong forceps, and this was firmly held by an assistant. Prior to the removal of this constrictor he secured the stump in the Kæberlé serre-nœud, having previously transixed it with two needles. The abdominal wound was then closed, and the pedicle was thoroughly smeared with Monsell's salt. At the present time, the beginning of the fifth day, the patient was doing well.

Dr. C. CLEVELAND exhibited a saw which he had invented for use in operations on the cervix uteri in cases in which the cicatricial tissue was considerable in amount and difficult to get at with the scissors. — Dr. HUNTER had used the instrument with advantage in two cases. [For a description of the instrument, see the "New York Medical Journal," Jan. 13, 1883, p. 54.]

B. F. DAWSON, M. D.,

FRANK P. FOSTER, M. D., *ex-officio*,

Committee on Publication.

A STATED MEETING was held November 21, 1882, Dr. CHARLES C. LEE, President, in the chair.

The PATHOLOGIST reported on the specimen presented by Dr. Hanks at the last meeting as follows:

The ovum, in a collapsed condition, measures 3 by 2½ ctm. It is covered all over with chorionic villi. The inside is smooth. At one spot is seen a small, round, flat body, 6 mm. long. It is all covered with a continuation of the inner membrane (amnios), which almost forms a kind of mesentery at its ends. Under the amniotic cover is only found a uniform yellow mass, without any visible organization. Judging by the size, the ovum is at least four weeks old. The small round body is the degenerated fetus.

Dr. H. J. GARRIGUES exhibited a *serre-nœud* as modified by Cintrac, of Paris. — The PRESIDENT thought the instrument was superior to the so-called improved *serre-nœud* of Weiss, of London.

HYSTERECTOMY.—Dr. BACHE McE, EMMET reported further on the case which he narrated at the last meeting of the society. The patient at that time was doing well, but suddenly extensive peritonitis developed, from which she died on the sixth day. There had been a good deal of sloughing of the abdominal wall about the stump, which was probably due to the free use of Monsell's salt, which had liquified and run down. The wire, which had been twisted so tightly about the pedicle, was found to be loose, showing that any tendency to hemorrhage that might have existed had been controlled by the tanning of the pedicle.

EMBEDDED PESSARY.—Dr. PAUL F. MUNDÉ presented a pessary which he had recently cut out of its bed in the vagina, seven years after its insertion.

PUNCTURE OF THE GRAVID UTERUS DURING THE PERFORMANCE OF OVARIOTOMY.—The PRESIDENT related the case as follows: The patient was a woman, twenty-eight years of age, who was sent to the Woman's Hospital by Dr. Hanks, for the removal of an ovarian cyst situated on the right side. The presence of the cyst was supposed to have been the cause of several miscar-

riages, and, as the patient was then three months pregnant, it was thought likely to prove so again. After making the usual incision for ovariectomy, the exact relation of the tumor to the uterus was ascertained. In turning the patient on her side, preparatory to puncturing the cyst, the latter was let go, and, unknown to Dr. Lee, the uterus took its place, rolling up into the abdominal incision, and was punctured instead. A large trocar penetrated the body of the womb to a depth of about two inches, entering at a point about two inches below the fundus. No fluid escaped when the trocar was withdrawn. The uterine wound was sewed up with carbolized silk, the long pedicle of the ovarian cyst was then ligated, the cyst was removed, and the abdominal wound was closed. Abortion had not occurred, and the patient was doing well. There had been vomiting, which was probably due to the influence of the anæsthetic. It was a noteworthy fact that the pedicle in this case was so long that the tumor, which was developed from the left ovary, lay upon the opposite side, in the region of the right ovary. The President thought the silk-worm suture which was used to close the abdominal wound possessed no advantages over the carbolized-silk ligature. It was much more liable to break, and was less easy to handle.

HEGAR'S OPERATION.—The PRESIDENT also related the following case: An unmarried woman, aged thirty-six years, was sent to the Woman's Hospital by Dr. Streeter, of Watertown, to have oophorectomy performed for the relief of symptoms due to a large multilocular fibroid tumor of the uterus. She had been suffering from menorrhagia and dysmenorrhœa for years, and had been unable to obtain relief. The tumor was as large as a fetus at the seventh month, lay principally on the right side of the abdominal cavity, and extended as high up as the umbilicus. The uterus could not have been extirpated without imminent danger to life. After an unsuccessful trial of medicinal treatment for a month, it was decided, at a consultation of the surgeons of the hospital, that Hegar's operation should be performed. The President removed the Fallopian tube on one side and both ovaries. The case was progressing favorably since the operation. The right ovary was bound down by adhesions, and extremely difficult to remove. Where adhesions were not present, however, the operation was not a difficult one. This was the third time it had been resorted to at the Woman's Hospital within a month, twice by Dr. Thomas, and once by himself. The patients were doing well. According to the statistics of the operation as given in the "American Journal of Obstetrics," January, 1880, out of one hundred and twenty cases only twenty-eight deaths had occurred. The success of the operation in relieving menorrhagia and dysmenorrhœa had been so great, and the dangers attending its performance had been so small, that the President thought it should be resorted to in these cases more frequently than had been done in the past.

With regard to the first case, Dr. GARRIGUES, who was present at the operation, said he did not think the trocar could have entered the amniotic cavity, else it would have caused miscarriage.

Dr. P. F. MUNDÉ mentioned several cases in which the gravid uterus had been accidentally punctured during an operation, but, so far as he knew, this case was unique in that the patient recovered without miscarriage.

Dr. C. S. WARD remarked that Dr. Thomas had lately performed Hegar's operation in a third case.

The PRESIDENT referred to Mr. Lawson Tait's experience regarding the difficulty of including the Fallopian tube in the same ligature with the ovary, and the necessity for removing the tubes in order to guard effectually against the occurrence of subsequent menstruation and a return of the symptoms.

CESAREAN SECTION.—Dr. H. J. GARRIGUES presented the uterus and its appendages, the pelvic bones, and a fetus, from a case in which he had recently performed Cesarean section. He remarked that, besides deformity of the pelvis, there was disease of the lumbar vertebrae, of the lungs, and of the heart, and that the patient was also suffering from several minor ailments. The last three lumbar vertebrae were fused together, and had caused a slight lordosis in this region; the sacrum was narrow, broader behind than in front, curved greatly backward, and also somewhat to the left, while the coccyx was curved somewhat to the right, the two bones presenting a lateral curve resembling in some degree the letter S. The superior surface of the ilium, instead of being concave, was flat anteriorly and convex posteriorly. The posterior superior spinous processes of the ilia were only six centimetres apart, instead of ten; the antero-posterior diameter of the inlet was greater than the lateral; the ilio-pectineal eminences were very prominent. The tuberosities of the ischia were only about one third the normal distance apart, and were very thin. The pubes appeared to be pushed forward and upward, and the curve between the pubic bones was much smaller than normal. In general, the pelvis was of a funnel shape; the plane of the brim was comparatively large, while the outlet was extremely small; and the ellipsis of the inlet was in the opposite direction from the normal. Dr. Garrigues believed that the deformity of the pelvis was secondary to caries of the lumbar vertebrae, and that it could be accounted for on mechanical principles, or by the action of the muscles.

HENRY J. GARRIGUES, M. D.,

B. F. DAWSON, M. D.,

FRANK P. FOSIER, M. D., *ex-officio*,
Committee on Publication.

A REGULAR meeting was held December 5, 1882, Dr. CHARLES C. LEE, President, in the chair.

RETROVERSION PESSARY, WITH AN ELASTIC SUPERIOR BOW.—Dr. T. A. EMMET showed a pessary which consisted of an Albert Smith pessary from which the upper bow had been cut off and replaced by a hollow soft-rubber bow, the ends of which were slipped over the arms left by the removal of the original bow. This soft-rubber bow was somewhat enlarged in its central portion, forming an air-cushion. Dr. Emmet stated that, while the instrument shown did not fully realize his idea, it was sufficient to show what the design was—namely, to furnish a pessary with a spring-like action exerted in an upward direction, combined with a yielding support to the uterus.

VAGINAL HYSTERECTOMY FOR EPITHELIOMA OF THE CERVIX.—Dr. W. C. BURKE, Jr., of Norwalk, Connecticut, who was present by invitation, showed a uterus which he had removed by the vaginal method twenty-four days before. The patient, who was doing well thus far, was thirty-seven years old. She had formerly been under Dr. Burke's care with stenosis of the os externum, accompanied by leucorrhœa and sterility. Mechanical dilatation rendered the cervical canal normal, and the patient ceased her attendance. Last March she again presented herself, for the relief of metrorrhagia, which, on examination, was found to be due to a cauliflower excrescence from the cervix. The cervix was amputated, but recently the disease had been found to have returned in the upper part of the cervix, and it was on this account that the uterus was removed. The organ was freely movable, and there were no evidences of infiltration of the tissues outside the uterus. Dr. Burke gave a minute description of the steps in the operation, and stated that the ovaries might have been removed without difficulty had it been thought advisable to remove them.

Dr. T. A. EMMET referred briefly to a case of his own which

had been related at a former meeting of the society, and expressed his feeling that the final success of such operations was a matter of considerable doubt. It seemed to him questionable, in view of the tendency of the disease to recur, whether the operation was to be recommended.

Dr. H. J. GARRIGUES thought it well to remove the ovaries in cases of hysterectomy wherever practicable, for they were apt to give rise to trouble if left behind, as shown by the formation of a hamatocoele in one of M. Péan's cases.

Dr. BURKE remarked that his patient had passed a menstrual period once since the operation, and without any flow.

Dr. W. M. POLK gave it as his decided impression that the most appropriate field for the operation of removal of the uterus was that of sarcomatous growths, which, while they showed a marked tendency to local recurrence, and in general proved fatal in the end, yet were not disposed to infect neighboring parts. Hence, in such cases removal of the uterus was more likely to get rid of the neoplasm permanently than in cases of carcinoma, besides which, the repeated minor operations rendered necessary in cases of sarcoma were apt to give rise to septicæmia in the end.

Dr. T. A. EMMET concurred in Dr. Polk's views.

DISSECTING METRITIS.—Dr. GARRIGUES presented a specimen of uterine tissue which had been cast off in a case under his observation, and referred to two other cases, one of which had been already reported to the society. The features of interest in the case now reported were, that the patient was not supposed at the time to be seriously ill, and also that the portion of tissue expelled was not in a septic condition at all, but was perfectly sound, like a piece of fresh beef. The specimen was examined microscopically, and found to consist of healthy uterine tissue undergoing the fatty degeneration of involution, the patient having been recently delivered. He again called attention to the great thinning of the wall of the uterus which took place in these cases, and to the danger, therefore, of rupture of the uterus in a subsequent delivery.

REMOVAL OF THE UTERINE APPENDAGES.—Dr. T. A. EMMET showed a number of specimens of dilated Fallopian tubes which had been given him by Mr. Lawson Tait, of Birmingham, England, and referred to Mr. Tait's practice of removing the uterine appendages frequently for the relief of chronic pelvic indurations which had heretofore been regarded as inflammatory thickening of the broad ligament, but which Mr. Tait looked upon as due to dilatation of the Fallopian tubes in all cases in which the usual treatment failed to produce a cure in the course of six months. Dr. Emmet added that Mr. Tait's results had been remarkably successful.

The following were the histories of three of the cases, as given him by Mr. Tait:

CASE I. PYOSALPINX.—Patient, aged twenty-eight years, had been a prostitute, and suffered several times from gonorrhœa. There was intense abdominal and pelvic pain, amounting to agony at times. She could not endure marital intercourse, and could walk only with difficulty. A mass was felt at the right of the uterus. On March 28, 1881, [Mr. Tait] opened the abdomen to remove the mass, but could not complete the operation on account of adhesions. On February 2, 1882, the case had got so much worse that I made a second attempt and succeeded. The patient made an easy recovery, and left the hospital free from pain.

CASE II. DOUBLE HYDROSALPINX.—The patient had suffered from persistent pain, with a tender mass on each side of the uterus. Menstruation was normal. Walking brought on pain, and intercourse was unendurable. I opened the abdomen and found all the pelvic organs matted together. Removed the uterine appendages. Both Fallopian tubes were adherent, occluded, and distended with serum.

CASE III.—Patient, aged thirty-eight years, gave birth to a child three years before, and had been ill ever since, with several attacks of acute peritonitis, from two of which she escaped with difficulty. The pelvic organs were fixed. Intercourse was unendurable. Two tender masses were felt behind the uterus. I opened the abdomen and found everything matted, the appendages completely adherent, the tubes distended with serum. The operation was very difficult to perform, and was attended with profuse hæmorrhage. The patient, however, made an easy recovery.

FIBROID TUMOR OF THE UTERUS.—Dr. T. A. EMMET also narrated this case, and stated that the point of interest connected with it related to the peculiar development of the tumor, which rendered the operation a very difficult and a fatal one. From the large tumor a spur was developed which fitted so tightly into the pelvic cavity that it seemed impossible to remove it. While attempting to do so, the uterus, with the mass, was torn from its attachments to the vagina and pelvic tissues, and a torrent of blood poured forth from the ruptured vessels. Although the hæmorrhage was finally controlled, the patient died really from the excessive loss of blood. Her condition had been such that, had the operation not been performed, doubtless death would have resulted within a few days, from the natural course of the disease. He mentioned the case simply as another which went to show the liability to the occurrence of unforeseen accidents.

Dr. P. F. MUNDÉ thought it desirable that we should possess some means of diagnosing enlargement of the Fallopian tubes by physical examination, rather than to undertake so serious a procedure as laparotomy on the strength of a mere inference. Was there, he asked, any such means?

Dr. F. P. FOSTER stated that he had diagnosed the condition in one instance from having recognized, on rectal examination, a body of a peculiar shape, resembling that of a fern head, occupying the situation of the Fallopian tube. He noticed that the specimens presented by Dr. Emmet were very much of this shape. In the case to which he referred no operation was performed, but he was as positive about the diagnosis as he could be about anything that was not actually demonstrated.

Reports on the Progress of Medicine.

QUARTERLY REPORT ON ANATOMY AND PHYSIOLOGY.

No. VIII.

By WILLIAM C. AYRES, M. D.

BRAIN WEIGHT AND BRAIN POWER.—Dr. J. P. H. Boileau is a full believer in the connection of the relative weight of a man's brain and his intellectual development. His article ("Lancet," Sept. 23, 1882) records a case in question, as follows: An officer, who was remarkably brilliant at school and in all of his relations of after-life, died of liver, lung, and brain disease. Post-mortem showed that his brain weighed 26,130 grains avoirdupois, or 59.72 ounces. It had also a specific gravity of 1.049. Thus, the weight of this brain exceeds all others usually quoted except Cuvier's, which weighed 64½ ounces, and Dr. Abercrombie's, 63 ounces. Since the average weight of a male adult's brain is under 50 ounces, and the specific gravity 1.036, the brain

of the officer was far in excess of the average. In fact, the specific gravity of 1.049 is the greatest on record.

THE MINUTE ANATOMY OF THE THYMUS.—In Mr. H. Watney's short note on the minute anatomy of the thymus ("Proc. of the Roy. Soc.," xxxiii, 216) we find that ciliated epithelial cells are found in the thymus of the dog. This is not the case in quite young animals, but ciliated epithelium can always be demonstrated in the thymus of a dog of over thirty months old, and often in those of much younger animals. In the older dogs the ciliated cells are found lining cysts, and the cysts appear to increase in size with the age of the animal. They take origin from connective-tissue corpuscles. These corpuscles, forming the network of the medullary portion, are in places matted together, forming concentric corpuscles of small size; in these masses small cavities are found, and the lining cells are transformed into ciliated cells.

In the thymus of the tortoise small cavities are found lined by columnar epithelium. The epithelial cells arise from connective-tissue corpuscles, the process being essentially the same as that just described in the dog.

The fluid in the lymph vessels leading from the thymus can be obtained by tying the vessels immediately after death. The lymph thus obtained contains considerably more colorless corpuscles than the lymph of the large lymphatics of the neck. The blood in the veins passing from the thymus does not appear to differ from the blood in the jugular vein.

THE INVISIBLE CORPUSCLES OF THE BLOOD.—Dr. R. Norris concludes his article, "On the Invisible Corpuscles of Mammalian and Oviparous Blood, and their Relation to Fibrin Formation and Coagulation" ("Lancet," Sept. 16, 23, 1882), by observing that the corpuscles recently observed in the circulating blood of the lower mammals by Professor Bizzozero, and called by him "blood-plates," are not newly discovered bodies, having been previously described by Professor Gulliver in 1846, and later, in 1872, by Professor Hughes Bennett, and more fully by himself in 1878, under the designation of "lymph discs." He says that this corpuscle possesses its fibrin-forming powers by virtue of being one of a series of corpuscles which he has distinguished as the "fugitive group," some of which are visible and others invisible in the blood. Of this series of corpuscles it is the earliest, and the one which yields the smallest amount of true fibrin, contributing more to the substance of the clot by furnishing granules, which adhere to the true fibrin and assist mechanically in the production of fibers, than in any other way. The true fibrin is not deposited, as is usually stated, from the liquid of the blood, but is the viscous, slimy, glairy, transparent material furnished by the fusion and confluence of the more developed corpuscles of the group—viz., by the invisible, colorless, and barely visible, slightly colored discs, which, after the blood is shed, undergo conversion into the well-known fibrin forms.

2. The elliptical corpuscles of the ovipara, like the discs of the mammals, are divisible into a permanent and fugitive group. The latter includes those ellipsoidal corpuscles the nuclei alone of which can be seen, and the cell-bodies of which are invisible, both while the blood is circulating and after it has been shed, and also a few of those corpuscles the outlines of which have become visible by the delicate tinting of the cell-bodies with hæmoglobin. It is the cell-bodies of these corpuscles which furnish the true fibrin—i. e., the material gelatinizes when the blood is shed. As in the case of the mammal blood, these corpuscles are the product of a gradual development of a colorless element, which can be traced back as far as the spleen lymphatics and the bone-marrow, and which is the true analogue of the primary lymph disc, from which all the morphological elements of mammal blood are directly or indirectly derived. This parent color-

less element of oviparous blood, therefore, corresponds to the so-called blood plates of Bizzozero.

3. In his recent investigation, Professor Legge, having overlooked the invisible cell-body of the transparent colorless ellipsoid of the ovipara, has seen its nucleus both in the circulating blood and in the blood removed from the vessels, and has described it as an independent body, and the analogue of the plates of Bizzozero, never dreaming that there existed around, and inclosing it, an unseen cell-body as large in most cases as that of the full-grown red corpuscle. No stronger proof could be afforded of the truth of his views, says Dr. Norris, than such an oversight, or of the incorrectness of Professor Legge's statements that no objection can be made to his conclusions, "on the ground of excessive delicacy, because when we are forewarned it is possible to observe a detail, however delicate." Professor Legge, he adds, has unwittingly demonstrated the truth of the position as to the absolute invisibility of these corpuscles under the conditions in which they normally exist.

4. With the well-known fact that water or aqueous solutions will remove the hæmoglobin from the red corpuscles, and render them so pale as to be scarcely visible, he has nothing whatever to do. These conditions are never present in any of his experiments, in addition to which there exist unmistakable characteristic differences, which enable the technically educated to distinguish at once between decolorized corpuscles and such as have never possessed hæmoglobin.

5. Although the invisible disc of the mammal has not yet been detected in the circulating blood, its equivalent and analogue in the lower vertebrata is, under these conditions, readily demonstrated; for, notwithstanding that its cell-body is as invisible as the mammal disc, its nucleus is distinctly visible, and forms the means of its identification both within and outside the vessels; and the problem to us is precisely the reverse of one of decolorization, for we have to bring into view—around a body which, in the circulation and outside it, presents itself and has been described as a free, colorless element—a cell-body having the size and form of cell-bodies of the ordinary red corpuscles, but devoid of hæmoglobin. Of the existence of the invisible corpuscles of oviparous blood we have, therefore, the crucial evidence furnished by its detection in the circulation.

THE STRUCTURE OF THE HEPATIC CELLS.—In his article styled a "preliminary account of the structure of the cells of the liver, and the changes which take place in them under various conditions" (*Proc. of the Roy. Soc.*, xxxiv, 220), Mr. J. N. Langley states that he has examined the liver-cells of a variety of animals, and they show the following common points of structure:

The protoplasm is arranged in the form of a network or honeycomb, the meshes or spaces of which are, in all parts of the cell, of much the same size; the outer parts of the cell are formed of a thin layer of slightly modified protoplasm, with which, however, the network is continuous. The spaces of the protoplasmic network are occupied by paraplasm or interfibrillar substance consisting of (1) spherical granules, probably protied in nature; (2) spherical globules of fat; (3) hyaline substance, filling up the spaces not occupied by the granules or globules. This substance consists partly of glycogen, and in part, probably, of a proteid.

As will be seen, this varies in many important particulars from the descriptions of Klein, Kupffer, Hering, etc.

When a section of the liver containing glycogen, after having been hardened in alcohol or osmic acid, is placed for some minutes in iodine solutions, certain parts of the interfibrillar substance of the liver-cells stain red-brown. Langley concludes that the portions so stained are glycogen, since glycogen can be extracted from them, since the amount of the red-staining sub-

stance varies directly with the amount of glycogen which can be extracted, since the coloration is just that produced when iodine is added to a little purified glycogen on a glass slide, and since it is rapidly dissolved by an amylolytic ferment, such as an aqueous or glycerin extract of the parotid of the rabbit.

During the summer months the liver of a hungry frog has granules scattered equally throughout the cell, and there is very little glycogen. During the long winter fast the cells change in appearance, the granules become more and more confined in the inner part of the cell, and form there a marked inner granular zone. The glycogen increases in amount, and is stored up chiefly in the outer part of the cell, where there are no granules. Osmic acid specimens in this condition show two distinct zones—an inner granular one, and an outer, apparently homogeneous one; the nucleus lies at the border of the two, or, if the outer zone is large, lies in it alone. When such a cell is treated with iodine, all, or nearly all, of the outer zone stains red-brown; around the granules also a varying amount of red-brown stained substance is found; the network of the inner zone, the granules, and the nucleus stain yellow. In these specimens the network of the outer part of the cell can not at all, or only very imperfectly, be made out. It is, however, seen in sections of the gland which have been hardened in chromic acid. It is continuous with the network of the inner part of the cell, but has wider spaces, and its bars are finer.

The disappearance of granules and the formation of glycogen which takes place in winter is only partly brought about by the absence of food; it is brought about in part, perhaps chiefly, by the low temperature, since, if in winter, when the granules are few and the glycogen plenty, the frog be kept at 20° C. for a week or a fortnight, the cells become granular throughout, and the glycogen largely disappears. If in summer the frog is kept cold, the reverse takes place.

Although, generally speaking, a decrease of the granules goes hand-in-hand with an increase of glycogen, yet a certain amount of variation in the one may take place without any variation in the other. Langley, therefore, considers the formation of both as independent processes. He thinks (from reasons stated) that the granules of the liver-cells are destined to give rise to some constituents of the bile.

As to the fat in the liver-cells, he says that, since in winter the amount of fat in the liver varies so much in frogs apparently alike, he does not feel justified in drawing any conclusions as to the changes occurring in digestion.

He mentions a peculiar fact, that the cells of a frog's bile-duct, where it runs through the pancreas, are ciliated; the pancreatic duct with non-ciliated cells joins it close to the small intestine.

He has taken the mole to observe the changes in the liver during digestion. In the hungry animal the protoplasmic network stretches throughout the cells with nearly equally sized meshes; in the spaces of the network is a small amount of hyaline substance, partly glycogen, and embedded in this are rather large granules. When the liver is examined, six to eight hours after digestion, there is a greater or less disappearance of granules from the center of the cells around the nucleus; the network has much wider spaces and thinner bars, and the spaces are for the most part filled with glycogen. In cases where changes are most marked, osmic acid specimens treated with iodine show a diffuse reddish-stained mass surrounding the nucleus; at the borders of the cell the yellow-stained network is seen, and one or two rows of granules; between these a little red-stained substance may usually be traced, continuous with the central mass of glycogen. The peripheric network and granules make the cell appear at first sight as if it had a very thick cell-wall. The network in the central part of the cell is

brought out by hardening a piece of liver in chromic acid and other reagents. In cells in which the digestive changes are less advanced, the glycogen may only partially surround the nucleus, or may be accumulated more on one side of it than elsewhere.

As in the liver of the frog, so in the mammalian liver, he takes the granules to be concerned in the formation of some of the substances found in the bile.

THE FUNCTION OF SECRETION.—In his lecture on the growth of our knowledge of the function of secretion ("Lancet," Aug. 26, Sept. 2, 1882), Mr. A. Gamgee, after paying tribute to the late lamented Darwin and Balfour, and giving especially the principal investigations of the latter, goes into the subject of his address by starting with the ideas of the ancients, and ending with the latest investigations on this most important subject, somewhat as follows: It was known to the ancients that there were organs which were concerned in the separation from the body of excrementitious substances, although the greatest doubt existed as to the organs to which such functions were to be ascribed. Thus, we find Hippocrates defining it as a characteristic of glands that they occur in moist parts of the body, but showing his ignorance of the true relation of glands to secretion by connecting them with the formation of hairs. The general opinion of the ancients, and, indeed, that which was taught by Galen, was that the glands were sieves, or colanders (*cola*), which served to drain off from the blood purely excrementitious substances. The liver and the kidneys were strangely enough removed from the group of the glands and placed among the *vi-cera*. The first author who really treated of the glands was Wharton, in his "*Adenographia sive glandularum totius corporis descriptio*." Although the author certainly added to the descriptive anatomy of secreting organs, his views on the functions of the glands were strangely fanciful and erroneous.

The glands he considered to be specially related to the nervous system, the viscera to the blood-vessels; such glands as the pancreas, and salivary and lachrymal glands being engaged in separating excrementitious substances from the nervous system. Gamgee then gives the researches of Malpighi and Ruysch and their followers.

It was, however, left for Professor E. H. Weber, of Leipsic, to completely demolish the Ruyschian hypothesis. By numerous researches on the salivary glands of birds and of mammals, and on the pancreas of birds, he established the general fact of the termination of gland ducts in blind extremities, though with modesty he put forward his opinions as confirming the inductions of Malpighi, expressing himself as follows: Admirably did Malpighi avail himself of the structure of the liver in the lower animals, and the embryo of the higher, as a step-ping-stone to his opinions; for the arrangement of the whole glandular system speaks for itself, inasmuch as it simply consists of single, compact, hollow, blind canals, more or less numerous, floating in a fluid which surrounds their organs; and, although these ramifications are drawn out between the branches of the blood-vessels, there is no immediate passage from one to the other.

As the great Johannes Müller was the first to duly appreciate the fact that all glands possessed of a duct were only involutions, more or less complex, of membranes, the largest number being involutions of the external investment of the body or of the membranes opening into its surface, he gives the result of his study relative to the structure of glands deduced from the anatomical study of individual organs. (Here follow the results of Müller's investigations under twelve heads.) Müller it was who first pointed out that "the peculiarity of secretions does not depend on the internal conformation of the glands," for, says he, "as I have sufficiently demonstrated, each secretion is in different animals the product of the most various glandular structures,

and very different fluids are secreted by glands of similar organization. The nature of the secretion depends, therefore, solely on the peculiar vital properties of the organic substance which forms the secreting canals, and which may remain the same, however different the conformation of the secreting cavities may be, while it may vary extremely, although the forms of the canal or ducts remain the same."

Purkinje announced the hypothesis that the nucleated epithelium which he discovered to line the gland ducts might exercise the secreting functions. Henle described, with great minuteness, the epithelium cells which line the surface of the ducts of the principal glands which form the superficial structures of mucous membranes, and Schwann suggested that this epithelium probably played a part in the act of secretion. It was, however, unquestionably the Scottish anatomist, John Goodsir, who established, in an indisputable manner, the fact that the essential and ultimate secreting structures in glands are the morphological units, the gland-cells. Goodsir was decidedly wrong in his further ideas as to the part of the cell which performed the secreting act, since in one publication he maintained that it was the cell-wall, in another the cell-nucleus, while today we consider that this action is the result of the activity of the living protoplasm of the cell.

Gamgee then gives the modern history of our knowledge concerning this most interesting branch of physiology, and concludes by a summary as follows: "The complicated studies of which I have attempted to give a brief sketch have led to our forming a certain, clear, general conception in reference to the process of secretion. They have brought into greater prominence the dignity, if I may use the expression, of the individual cell. The process of secretion appears as the result of the combined work of a large number of units. Each, after the manner of an independent organism, uses oxygen, forms CO_2 , evolves heat, and derives its nutriment from the medium in which it lives, and performs chemical operations of which the results only are imperfectly known to us. So long as the protoplasm is living, the gland-cell retains its power of discharging its functions, and in many cases does so as long as the intercellular liquid furnishes it with the materials required. In some cases, however, the gland-cells are specially sensitive to a variation in the composition of the nutrient liquid, certain constituents of which appear to stimulate the protoplasm to increased activity. In the higher animals the cells, particularly in certain glands, are in relation to nerves which, when stimulated, affect in a remarkable manner the transformations of their protoplasm, leading to an increased consumption of oxygen, an increased production of carbonic acid, an increased evolution of heat, and an increased production of those matters which the cell eliminates and which constitute the secretion."

THE MOTOR FUNCTIONS OF THE BRAIN.—Rosenthal ("Med. Jahrb.," 1882, iii) gives a general review of what we know on the subject, culled from the writings of the various authors. He criticises them to some extent, and thus relates his own experience, gained both from experiment and clinical observation. The results of his experience go to show that an irritative lesion of the pyramidal fibers and the cells connected by sudden and very vehement hæmorrhage in the various parts, cortex, centrum ovale, inner capsule, can produce tonic muscular spasms. This can happen without rupture. The greater lesions which cause rupture toward the convexity or toward the ventricle will produce a more rapid and lasting rigidity. The hæmorrhage into the lateral ventricle, which is produced by less pressure, may not affect the pyramidal fibers of the capsule interna; in this case there will be present the usual increase of intracranial pressure and apoplectic symptoms, but there will be no convulsion or muscular rigidity.

He shows, further, that the irritative lesion of the above parts, and not the consequences, produces the muscular rigidity. This is demonstrated by the following experiment: In a medium-sized dog the cord is cut high up in the pectoral portion, and artificial respiration set up; the hind paws of the animal will appear paralyzed, while those in front will undergo tonic spasms. Every mechanical or electric irritation of the muscle or nerves will cause increase in the spasms.

Many clinical, anatomical, and experimental facts tend to prove that the doctrine which we have heretofore held as to the motor significance of the corpora striata system is not beyond question; they seem to show that the motor centers are located in the capsula interna. He says he would not state that the corpora striata have no relation to mobility, since, in the sense of Magendie, they may govern the co-ordination of motions. According to Duret, animals which have had their corpus striatum divided lose the power of progressive motion; but more extended and careful study of this in man must be sought after. The opinions of Charcot on this subject he cites from a lecture from that author in the following manner: "Je suis tout disposé à croire comme vous, que la lésion des corps opto-striés ne produit l'hémiplégie qu'en tant, que cette lésion intéresse directement ou par compression le faisceau pyramidal de la capsule interne. Il y a longtemps, que je ne me suis plus occupé de la question. Je la reprendrai à la première occasion, puisqu'elle vous intéresse."

THE PROPAGATION OF INHIBITORY EXCITATION IN THE MEDULLA OBLONGATA.—Mr. Kronecker and Mr. Meltzer ("Proc. of the Roy. Soc.," xxxiii, 216) arrive at the following conclusions:

1. That the beginning of every act of swallowing not only excites the œsophageal contraction related to it, but at the same time restrains the contraction excited shortly before it, but which has not yet occurred. This inhibition is capable of preventing the contraction even immediately prior to its appearance. It is, therefore, to be concluded that the restraining excitation traversing the direct motor tracts outruns the motor excitation advancing through the ganglion groups.

2. The second motor irritation is effective only when the contraction following the first has passed. The anatomical tracts, along which this inhibition is conducted, they have found to be the ramifications of the ninth pair of cranial nerves (glossopharyngeal).

3. If the trunk of the glossopharyngeal is irritated, no movement of deglutition results, in spite of the strongest excitation to deglutition, produced by filling of the pharynx with fluid, or by stimulation of the superior laryngeal nerves. Both the first reflex act of swallowing and the œsophageal contraction are for the time in abeyance.

4. If the pharyngeal branches only are irritated, then the inhibitory phenomenon appears in the cervical or in the thoracic portion of the œsophagus.

5. If the glossopharyngeal nerve be cut through, the œsophagus falls into tonic spasm, which may last longer than one day.

They further conclude that the excitations which reach their center in the medulla oblongata through the glossopharyngeal nerve exert an inhibitory influence, not only in the origins of those vagus fibers which supply the œsophagus, but also on the ends of the vagus fibers which excite the movements of respiration and restrain those of the heart. Lastly, the inhibitory influences extend also to the center in the medulla, regulating the blood-vessels. This can be shown in normal living man. One can, by swallowing easily, observe the following: 1. During each act of swallowing the pulse frequency increases. 2. During a series of acts the need of respiration decreases. 3. During each act of swallowing the blood pressure falls in the aortic

system. This remarkable proposition therefore follows: that the excitations which are conveyed to the center, along the tracts of the inhibitory nerves, extend in the character of inhibitions to the neighboring centers.

Continued experiments on these inhibitory nerves promise specially interesting disclosures, because they can be set into activity through normal excitation voluntarily produced, which is not the case with the vagus.

THE WHITE CORPUSCLES AND THE COAGULATION OF THE BLOOD.—Dr. L. C. Wooldridge ("Proc. of the Roy. Soc.," xxxii, 214) gives many interesting conclusions regarding the relation of the white corpuscles to the coagulation of the blood. The leucocytes (essentially white blood corpuscles) were obtained by finely dividing the mesenteric glands of a calf and gently rubbing the fragments in a mortar with a one-half-per-cent. solution of salt. By filtration through a fine cloth the cells passed through, and were washed out with a one-half-per-cent. solution of Na Cl by means of the centrifugal machine. The cells were apparently unchanged under the microscope. They were then suspended in a little normal salt solution and subjected to various experiments, the most important of which showed that the lymph cells are changed by simple chemical reagents into a substance closely resembling fibrin. If to one volume of suspended cells an equal volume of ten-per-cent. solution of common salt be added, the whole is immediately converted into a peculiar semi-transparent jelly. If this be poured into water, or into a one-per-cent. solution of salt, it becomes immediately opaque. The microscope shows that the cells as such have disappeared. Only nuclei embedded in a distinctly fibrous ground substance are visible. The same for sulphate of magnesium, distilled water, etc.

To show the behavior of leucocytes toward plasma, he collects the plasma of a dog by injecting peptone. This he calls peptone plasma. After experiments he concludes that peptone plasma behaves in the same way toward the cells as salt, magnesium, or water. When peptone plasma is the destroying reagent, the result is certainly fibrin, and the action is perfectly independent of the presence of a fibrinogenic substance in the plasma, since there could be no such substance found in it. He concludes that the plasma changes the cells into fibrin, for various reasons which he gives in full. He also shows that coagulation is the result of a change in the plasma, and has nothing to do with the vital properties of the cells; also, that the conversion of the white cells into fibrin is quite independent of the presence of any "fibrinogen" substance. Fibrinogen is present in "living" plasma, yet the dead cells produce no coagulation. Fibrinogen was absent from the peptone plasma, which still gave practically unlimited quantities of fibrin with lymph-cells. Alexander Schmidt has shown that white blood-cells do unquestionably disappear as such during normal coagulation of the blood, and Wooldridge confirms his statement. He therefore thinks that he is justified in saying that there are two essential processes in the coagulation of the blood, one of which has been hitherto entirely wrongly appreciated or overlooked. This is that the "dead" plasma converts the white corpuscles directly into fibrin. At the same time, however, that this occurs, a substance is liberated from the cells which converts the fibrinogen into fibrin. The substance which is liberated from the cells is fibrin ferment.

THE ACTION OF THE VERTEBLES OF THE HEART.—Dr. G. A. Gibson's paper ("Edinburgh Med. Jour.," Aug., 1882) is mainly historical, but is interesting, since it gives about all we know concerning the action of the auricles in health and disease. For instance, he refers to the fact that the contemporaries of Senac and Haller (1749-57) well appreciated the action of the venæ cavae and pulmonales; it was a matter of every-day

observation that the superior vena cava continued to pulsate after the auricles and ventricles had become motionless. During the closing years of the last century and the first half of our own no such property was allowed to veins; as a matter of fact, in the memoirs of Raciborski, the statements of Haller are categorically denied, and attributed to mistakes in observation.

The discovery by Wharton Jones of the rhythmic pulsation of the veins of the bat's wings was of much importance, for it turned the attention of physiologists to the well-nigh forgotten fact that the venous walls have the power of independent contractions in situations requiring such aid. Now, by the observations of Colin, and of Lauder Brunton and Fayer, the subject may be regarded as beyond discussion. As before mentioned, the paper is mainly historical, and, since it is illustrated by numerous heart curves on wood, it would be well worth the reading.

THE DURATION OF THE VENTRICULAR SYSTOLE.—The heart tracings which are recorded in Dr. P. M. Chapman's paper ("Brit. Med. Jour.," Ang. 19, 1882) were obtained by Dr. Burdon Sanderson's cardiograph, and, since the instrument is a delicate one, the results seem to be reliable. The measurements of the duration of the systole for the different pulse frequencies are made from the same cases at rest, and also when the pulse frequency varies from excitement, from exertion, and from immersion in the hot-air chamber of a Turkish bath. Many tracings follow. It is interesting to note in the tracing the very rapid diminution in the duration of systole. In the Turkish bath the temperature was 140° . The temperature of the body never rose above 102° Fahr. After the cold douche it is remarkable that the heart's rapidity returns to the same number of beats as before the bath, and that, as reaction sets in, there is again a diminution in the duration of systole.

He then gives tracings which show that, although the pulse frequency may actually increase, the systole lengthens as the patient cools; also experiments which seem to determine that the temperature of the blood has a distinct influence in shortening the duration of ventricular systole. This shortening was unaccompanied with any feeling of faintness whatever in the patients experimented on. His experiments also furnish the heart tracings of persons who were brought from the bath in a fainting condition and examined while unconscious.

He includes in his report the lengths of systole in pulse rates varying from 130 beats to 46 beats. The length of ventricular systole in the former he gives as $0.2100''$, while in the latter it is $0.3600''$. Occasionally, however, a variation in the duration of systole of $0.04''$ to $0.06''$ may be met with for the same pulse frequency without any assignable cause; he therefore invites further investigations to clear up the mystery.

Experiments of this nature require much labor and care, and the thirty-one wood-cuts showing his results are certainly worthy of a close study.

THE RHYTHM OF THE FROG'S HEART AND THE ACTION OF THE VAGUS NERVE.—The method employed by Mr. W. H. Gaskell in his study on "The Rhythm of the Heart of the Frog and the Nature of the Actions of the Vagus Nerve" ("Proc. of the Roy. Soc.," xxxiii, 217) deserves to be stated. It is: The heart, with the vagus nerve intact, having been removed from the body together with a portion of the cesophagus, a thread is tied to the very apex of the ventricle, and another to the loose flap, which is disclosed at the junction of the two auricles when the two aortic trunks are cut away. The piece of the cesophagus removed with the heart is held firmly in a suitable holder, and the heart suspended between two horizontal levers by means of two threads, which are attached to the auricle and ventricle. Between the two levers a clamp is placed, the edge of which can be approximated to any degree by means of a fine micrometer

screw; the two limbs of this clamp are placed one on each side of the suspended heart, and, by means of the micrometer screw, the tissue between the two edges can be simply held firm or compressed to any required extent. In this way, with the clamp in the auriculo-ventricular groove, the beats of both auricles and ventricle are registered simultaneously and separately; the contractions of the auricles pull the upper lever downward, those of the ventricle the lower lever upward. Similarly, by varying the position of the clamp, the contractions of the two adjacent portions of the heart can be studied, etc.; heat, cold, and poisons can be applied to the tissue on the one side of the clamp, and not on the other; and under all these various conditions the effects of stimulation of the vagus can be observed. The paper is divided into two parts: I. On the rhythm of the heart. II. On the action of the vagus nerve. Conclusions arrived at in the first part are: 1. The rhythm of the heart is caused by discrete motor impulses passing to the muscular tissue from certain motor ganglia. 2. In order that each one of these impulses may produce a contraction of the ventricle, a due relation must exist between the strength of the impulse and the excitability of the ventricular muscle. 3. When each impulse is inefficient to cause a contraction of the ventricle, the ventricular muscle has the power of summing up the effects of two or more of these inefficient impulses, and so continues to beat rhythmically, but no longer synchronously with every impulse. 4. The most satisfactory explanation of this summation process is as follows: Every impulse which is inefficient to produce a muscular contraction increases the excitability of the muscle, and, therefore, makes it easier for a second similar impulse to cause a contraction. 5. The impulses can be made inefficient to produce contractions synchronous with them by lowering sufficiently the excitability of the ventricle, as is seen in the action of poisons, even although the rate and strength of the impulses remain unaltered. 6. The impulses can also be made inefficient, when the excitability of the muscle is unchanged, by diminishing the strength of the impulses, as is seen in the effects of compressing the tissue between the ventricle and the motor ganglia, or of heating the auricles and sinus without heating the ventricle. 7. There is a limit to the extent to which a series of inefficient impulses can raise the excitability of the muscle, so that the ventricle can remain absolutely quiescent, even although the impulses still pass to it, when those impulses are sufficiently weakened.

In Part II the action of the vagus nerve is considered, and it is shown that its stimulation produces a most marked effect upon the force of the contractions, both of the auricles and ventricle, entirely independent of any alteration of rhythm. The curves obtained can be classified under the three following types:

1. Complete quiescence of both ventricle and auricles, followed by contractions which at first are scarcely visible, but which rapidly increase in size until, at the maximum, they are much greater than before the stimulation of the nerve. From this maximum they very gradually decrease until the original size of contraction is again reached.
2. During the stimulation no quiescence of either ventricle or auricles, but simply a diminution of the size of the contractions, followed by a rapid and marked augmentation of the contractions beyond the original height, and then a slow, gradual diminution to the size obtaining before the nerve was stimulated.
3. No primary diminution, but from the commencement of the stimulation the beats increase in size, and after a time gradually return again to the normal size. Between these three types every conceivable variation may occur, so that a series of curves may be selected in which no line of demarkation can be drawn between complete primary quiescence (or inhibition) on

the one hand, and a simple primary augmentation of the size of the contractions on the other.

The curves alone show that the *vagus* is able to cause a standstill by diminishing the force of the contractions down to quiescence; this is further shown by the fact that standstill of the ventricle alone can occur while the auricles are beating with accelerated or unaltered rhythm but diminished force, or even when from the commencement of the stimulation the force of the auricular contractions is increased.

The conclusion is drawn that the variations in the effects produced by stimulation of the *vagus* on the force of the contractions are dependent essentially upon the condition of nutrition of the heart; and possibly for the same cause the *vagus* tends to lose all power of producing slowing after the heart has been suspended in the apparatus, for in most cases acceleration only is seen, although slowing occurred on stimulation before the heart was cut out, and, apparently, slowing is more likely to occur immediately after the suspension of the heart than later. Further, he concludes, from experiments, that stimulation of the *vagus* acts upon the muscular tissue of the ventricle in such a way as to diminish its excitability and lower its tonicity when it reduces the force of the ventricular contractions, while it increases its excitability, and possibly also increases its tonicity when it augments the contraction force.

Finally, it is shown that atropine removes the whole action of the *vagus* stimulation, and the effects of the local application of curare, muscarine, and atropine are described and discussed. In conclusion, the author suggests that a series of formative processes is going on in both the muscular tissue and the motor ganglia of the heart similar to those which occur in gland-cells, and that the *vagus* produces all its effects by increasing the activity of these processes, and not because it contains a multiplicity of fibers, each of which possesses a different function.

THE ACTION OF ELECTRICITY ON THE FROG'S HEART.—From the results of the recorded experiments conducted on the frog's heart in its normal position and still exercising its circulatory functions, Brunton and Cash ("Proc. of the Roy. Soc.," xxxii, 214) have found:

1. That electrical stimulation by a single induced shock has either an obvious effect on the contraction and rhythm of the organ, or no such effect is apparent.

2. That the effect is modified by (a) the time of the cardiac cycle in which stimulation falls; (b) the strength of the stimulation applied; (c) the area of the heart to which stimulation is applied; (d) the action of heat, cold, and drugs. Thus, cold prolongs the systole, the refractory period, and the latency of an induced contraction; while strychnine, leaving the curve of the systole unaltered, lengthens the refractory period to a marked degree.

THE PERIPHERAL LYMPHATICS.—In a lecture before the French Academy ("Gaz. hebdom. de méd. et de chir.," Sept. 15, 1882) Onimus discusses the importance of the peripheric-lymphatic system in the changes of color of the skin. These lymph spaces contain a translucent, pale-yellow fluid, which sometimes gives a light opalescent coloration. It has a great influence on the color of the skin, since, if this lymph is abundant, the red color of the blood will thereby be subdued and the skin will appear pale. If it is present in small quantities, the red will predominate and the skin will appear flushed; therefore, both the peripheric-lymphatic and blood-vessel systems are important in this coloration. We sometimes notice that after moderate mechanical excitations the color of the skin will remain constant for some hours, and be vigorously confined to one place. This is caused by the lymphatic system, since when the blood is expelled from a part of its vessels it returns into

them in a very short time, while this is not the case with the contents of the lymphatic system. In such cases, when the lymph vessels are depleted the skin will appear red, and as they begin to be refilled, it has a rosy hue.

If the mechanical excitation has been violent, the changes which occur in the cutaneous coloration are more complicated, because under these conditions the blood returns with too much force, and the parts of the blood column along the walls of the vessels are taken up by blood which has an abnormal quantity of the red-blood corpuscles. Under such circumstances the skin has a vivid red color, since the lymph is absent at the same time.

In many persons, and especially women and children or those essentially lymphatic, we may notice around the place of mechanical excitation that small whitish places commence to form, which increase by degrees, finally forming a surface of a rosy hue. This is caused by accumulations of the returning lymph. If such places are pricked with a needle, they emit a yellowish serous drop, which will be found to be lymph.

Again, in faradization of the skin we notice a very marked rubefaction. We know, however, that this produces a diminution in the caliber of the blood-vessels, and we are therefore at a loss to explain the red coloration except by considering it due to the absence of the lymph.

After the constant current, we notice that the redness is more rapid and more uniform at the positive pole, whereas at the negative pole there is frequently a central, elevated pale spot, which appears as if it contained a milky fluid. The various conditions which regulate the amount of blood in its vessels, such as muscular walls and the "vis a tergo," are entirely different from those which regulate the flow of lymph, which accounts for the above-mentioned differences in the refilling of the lymphatic and sanguineous systems.

The changes in the coloration of the skin in the various diseases are, therefore, probably due to the conditions of both of these systems. Accordingly, all such medications as frictions, electrizations, and baths should be used and studied for the influence they have on the peripheric-lymphatic system. They owe their effect in this way to the above conditions, and, therefore, have much more influence in persons of lymphatic temperaments.

THE PHYSIOLOGY OF SUGAR IN THE SYSTEM.—In his article on "A New Line of Research bearing on the Physiology of Sugar in the Animal System" ("Proc. of the Roy. Soc.," xxxii, 214), Dr. F. W. Pavy concludes that bernardin (glycogen) does not undergo any significant transformation into sugar in contact with blood. Bernardin exists to a distinctly notable extent as a normal constituent of blood. The evidence derivable from the observations recorded on the addition of bernardin to the blood and its subsequent recovery, and on its extraction from the liver by boiling water on successive days, and by water at 300° Fahr., tends to show that bernardin enters into feeble combination with nitrogenous matter. Bernardin exists in notable amount, not only in muscle, as has been previously known, but also in the spleen, pancreas, kidney, and brain. (He has only examined these structures.) It also exists in notable amount in the white and yolk of eggs. These several products also contain a cupric-oxide reducing substance, which is extracted by alcohol, and which, in most instances, possesses the character of glucose, but specially, in the case of muscle, the character of maltose. Through the existence of glycogen throughout the system, as has been represented, we have a substance occupying a parallel position to albumin—viz., existing in a colloidal state, and thus adapted to retention in the body, instead of passing off as a diffusible substance, as glucose tends to do.

CARBOLIZED SOAP-SHEETS.

THE New York agent of Messrs. Reithoffer & Neffe, of Vienna, has favored us with a specimen of Buczkowski's patented carbolized soap-sheets. They are arranged in the form of a little book, easily carried in the waistcoat-pocket. The leaves consist of very thin paper coated on both sides with a thick layer of carbolized soap. We have kept the specimen about two months, and are unable to perceive that during that time the percentage of carbohc acid has diminished notably, although the book has remained open in a warm room. We therefore regard the enduring properties of the sheets, as regards their disinfectant action, as all that could reasonably be expected. We understand, however, that the makers prepare like books with the leaves impregnated with other medicinal substances, also those that are not medicated, but simply perfumed.

The method of using this device is, to tear a leaf out and rub it in the wet hands. The saponaceous coating dissolves at once, leaving a mere pellet of paper. The convenience to physicians of carrying one of these little books in the pocket, rather than any liquid disinfectant preparation, need scarcely be mentioned. They will doubtless commend themselves also to travelers, since they can thus avoid the conventional cake of soap that has been used by they know not how many persons before them.

Miscellany.

THE MASSACHUSETTS STATE BOARD OF HEALTH.—"The Boston Medical and Surgical Journal" announces the resignation of Dr. Alfred Hosmer from the Board of Health, Lunacy, and Charity, and that of Dr. H. P. Walcott the position of Health Officer of the board. The latter gentleman has been appointed to the seat in the board made vacant by Dr. Hosmer's resignation, and Dr. S. W. Abbott, of Wakefield, succeeds to Dr. Walcott's position.

THE ALBANY COUNTY SOCIETY.—At the last annual meeting of the Medical Society of the County of Albany, as we learn from "The Medical Annals," the following officers were elected: *President*, Dr. John M. Bigelow; *Vice-President*, Dr. B. U. Stenberg; *Secretary*, Dr. Lorenzo Hale; *Treasurer*, Dr. G. L. Ullman; *Censors*, Dr. F. C. Curtis, Dr. J. S. Mosher, Dr. J. U. Haynes, Dr. A. Shiland, and Dr. D. H. Cook.

DEATH OF DR. WILLIAM PIRRIE.—Recent English journals record the death of William Pirrie, M. D., LL. D., Professor of Surgery in the University of Aberdeen, at the age of seventy-five. For many years Dr. Pirrie was one of the leading surgeons of the North of Scotland, and he was well known in this country by his treatise on the "Principles and Practice of Surgery."

A PRIZE ESSAY ON THE PREVENTION OF BLINDNESS.—The fifth International Congress of Hygiene, which will meet at The Hague, Holland, in 1884, will award the prize of two thousand francs (£80 sterling), offered by the London Society for the Prevention of Blindness, to the author of the best essay, written in English, French, German, or Italian, on the causes of blindness and the practical means for preventing it. Besides this prize, the International Society for the Improvement of the Condition of the Blind reserves to itself the right to award a second prize of one thousand francs (£40 sterling), or two prizes of five hundred francs (£20 sterling), each and a silver gilt medal with a diploma, should it see fit, to such of the essays as should, in the opinion of the international jury for the principal prize, be deserving of it; the last mentioned prizes will be distributed at the centenary festival of the first blind institution founded by Haüy, which will take place in Paris in 1834.

The fourth International Congress of Hygiene, which met at Geneva, in September, 1882, has adopted for this competition the following programme, as prepared by the London Society for the Prevention of Blindness: I. The Study of the Causes of Blindness: a. Hereditary causes; diseases of parents, consanguineous intermarriages. b. Infectious eye diseases; various inflammations of the eyes. c. School period and time of apprenticeship, progressive shortsightedness, etc. d. General diseases; diatheses, various fevers; chronic poisoning, etc. e. Trade influences; wounds and accidents, etc.; sympathetic ophthalmia. f. Social and climatic influences; contagious ophthalmias; unhealthy habitations; defective lighting, etc. g. Neglect of treatment and bad treatment of eye affections. II. The Study of Practical Preventive Means: a. Legislative means. b. Hygienic and professional means. c. Educational means. d. Medical and philanthropic means.

The International Jury, elected by the Geneva Congress, for the purpose of judging the essays, consists of: Holland—Dr. Snellen, Professor of Ophthalmology, Utrecht. Germany—Dr. Varrentrapp, Frankfurt; Dr. H. Cohn, Professor of Ophthalmology, Breslau. France—Dr. Fieuzal, Physician to the Hospice des Quinze-Vingts, Paris; Dr. Layet, Professor of Hygiene, Bordeaux. Italy—Dr. Reymond, Professor of Ophthalmology, Turin; Dr. Sormani, Professor of Hygiene, Pavia. England—Mr. Streetfield, Professor of Ophthalmology, University College, London; Dr. Roth, Honorary Secretary and Treasurer (*pro tem.*) of the Society for the Prevention of Blindness, London. Switzerland—Dr. Dufour, of the Ophthalmic Hospital, Lausanne; Dr. Appia, Geneva; Dr. Haltenhoff, Lecturer on Ophthalmology, Geneva, and Secretary to the Jury. Dr. Appia and Dr. Varrentrapp having resigned, the jury completed its number by electing Dr. Courserant, Oculist, Paris, and Dr. Berlin, Professor of Ophthalmology, Stuttgart.

Those essays to which prizes have been awarded will become the property of the Society for the Prevention of Blindness, and of the International Society for the Amelioration of the Condition of the Blind, who will be at liberty to publish them in whole or in part in several languages, in order to make them useful in the way they consider best. The manuscripts for competition are to be sent to Dr. Haltenhoff, Geneva, Switzerland, Secretary to the Jury, not later than the 31st of March, 1884. Every manuscript must be distinguished by a motto, which is also to be written on a sealed envelope containing the name, Christian name, titles and address of the author. The envelopes will not be opened until after the award of the jury.

THE "ANNALS OF ANATOMY AND SURGERY."—At the close of the third year of the publication of the "Annals of Anatomy and Surgery" the editors indulge in some reflections as to the reason of its being and the aims of its future. It still remains, they say, the only journal devoted to surgery, and to anatomy as related to surgery, published in the English language. That it should be maintained, there is ample reason in the number and quality of the special workers in this field, in the character of the problems which engross its students, and in the rapid strides toward scientific precision which surgical practice has witnessed within the past two decades.

However it may once have been, a monthly or a quarterly which now attempts to include in its compass the whole of medicine is at once crippled by the size of the field, but, if it restricts itself to a special department, it presents the happiest union of the elements needed for the best presentation of whatever may be of permanent value in that department. The specialization of journals is thus but the natural result of that specialization of study and practice which is the inevitable result of the growth of knowledge. The power of this tendency to specialization has shown itself in the gradual development of this journal from being the simple record of a special local society to a point where it may presume to claim consideration as an exponent of American surgery in general. In order to favor the future development of the journal, the Anatomical and Surgical Society of Brooklyn, by whose direction and support it was inaugurated, have relinquished their special interest in it, and henceforth its editors will be solely responsible for its contents and character.

We heartily commend the "Annals" as a carefully prepared mirror of the progress of anatomy and surgery, and as a particularly handsome journal.

BORIC ACID.—Neumann has, in view of the extensive use of boric acid, instituted experiments to ascertain more precisely its physiological effects. A dog of the weight of fifteen kilogrammes presented no marked symptoms from a dose of five or six grammes, but a marked fall in internal temperature was produced. Larger doses caused also vomiting and diarrhoea. A three-per-cent. solution injected into the pleural or peritoneal cavity did not cause inflammation of the serous membrane; but, whenever the quantity injected exceeded certain limits, the animals died from paralysis of the motor nerves and muscles. Results of identical character were also furnished by experiments on rabbits and young pigs. Boric acid was given to horses affected with glanders up to forty-five grammes (? a dose), and the nasal ulcerations were treated with the same substance. A transient amelioration in the condition of the animals was the result, but none recovered. Boric acid may thus be regarded as not only an antiputrescent, but also an antipyretic, comparable to carbolic acid.—*The Lancet.*

FERRUGINOUS LIVERS.—The presence of an excess of iron in the livers of anemic patients is a curious fact, of which several instances have been described in Germany. One case was described by Stahel; and Lindenlang, in the liver of a patient with purpura, found a considerable excess of iron. Marchand has lately described the liver of a phthisical patient, aged sixty years, which presented an unusual brownish-red color associated with evident cirrhosis. The microscope showed an infiltration of the hepatic cells and of the interstitial connective tissue by pigmentary corpuscles, which gave the characteristic test for iron with yellow ferrocyanide. A chemical analysis showed that the ashes contained not less than thirty per cent. of iron. It has been supposed that the excess of iron is the result of an abnormal destruction of red blood corpuscles in the organ, but it is open to question whether it is more than the result of the free administration of iron by the mouth.—*The Lancet.*

THE INFLUENCE OF ALTITUDE ON HEALTH.—The subject of this was one of special local interest) was treated at some length at the Geneva Congress by the president, Dr. Lombard. He attached particular importance to the hygienic advantages to be derived from moderate altitudes of, say, fifteen hundred to three thousand feet, in contradistinction to the effects produced by the more lofty portions of the mountainous regions of Switzerland and other countries. He dwelt on the

advantages of the Engadine as a residence for persons of consumptive tendencies, and also described some of the sanatoria in the Himalaya Mountains. M. Paul Bert, while agreeing with the general principles laid down by Dr. Lombard, contributed some interesting details as to experiments he had made in his own person (in conjunction with several scientific friends) with a view to proving the efficacy of the inhalation of oxygen as a restorative process in cases where the excessive rarefaction of the atmosphere at extreme altitudes produces a kind of asphyxia. The general tendency of M. Bert's theory is to supply the oxygen which is wanting in the air at such heights, and the experiments he and his friends made consisted of the production, by artificial means, of this "mountain-sickness," and its removal by the inhalation of air with a full proportion of oxygen. The subsequent experiences of aeronauts tend also to prove that the inhalation of oxygen is an immediate remedy for the quickening of the pulse and of the respiration, the headache, somnolence, and partial loss of reason, which are among the symptoms of the injurious effects of extreme altitudes.—*The Lancet*.

THE REGISTRATION OF VITAL STATISTICS.—The subject of registration of vital statistics is one of the most important, and at the same time most difficult, in sanitary as well as social science. Its difficulties are in part due to its apparent simplicity. Before studying it, and attempting to obtain practical results, almost every one is disposed to think that he understands it, and is quite ready, not only to undertake the duties of registrar or census superintendent, but to prepare a law or ordinance regulating the matter. After one has investigated the matter a little, and has become somewhat acquainted with the methods in use, it is not unlikely that he will suppose that he has made some remarkable discoveries of causes of error, imperfect returns, insufficient tabulations, and erroneous conclusions, and will thereupon proceed to prepare a paper criticising the work of his pre-decessors and proposing reform. It is probable, however, as he continues his studies, that he will find that his discoveries are not new, that there are various practical objections to his proposed improvements, and that it is much easier to confine his essay to denunciation of that which is, than to point out clearly and definitely that which ought to be, and which is at the same time practicable. This has been the experience of Dr. John S. Billings, as related in a paper published in the "*American Journal of the Medical Sciences*" for January, 1883; he has, however, succeeded in making a valuable report on the systems of registration of vital statistics in nearly all countries, showing the value of such statistics for legal purposes, in identifying individuals in their relations to their families and the community, for the prevention and detection of crime, for furnishing data for sanitary purposes, and as bearing on the laws of human development.

SIMONNOT'S ANTI-BLENNORRHOIC BOLUSES.—The "*Journal de médecine de Paris*" gives the following formul

Copaiba balsam.....	25 grammes;
powdered cubeb.....	122 "
wax.....	12 "
powdered rhatany.....	9 "
carbonate of magnesium.....	6 "

To be made into boluses of 1 gramme each, which are to be rolled in subcarbonate of iron, and coated with an ethereal solution of tolu balsam and mastic.

CHLOROFORM IN LABOR.—Dr. Fancourt Barnes ("*Brit. Med. Jour.*," Oct. 21, 1882) attributes the comparative innocuousness of chloroform in obstetric practice to the physiological increase of power gained by the heart during pregnancy.

It is said that in Ontario there is one physician to every 1,125 inhabitants.

THE CHANCE OF A EUROPEAN CHOLERA EPIDEMIC.—Already there is a moderate prevalence of cholera in Arabia, and its extension to Europe can be prevented, says a recent writer in the "*Revue Médicale*," only by stringent action by the Turkish government and by the British in Egypt.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL has thus far met with gratifying success. The second term opens January 8, 1883, and continues until April 28th without intermission. It is hoped that, with its enlarged accommodations, improved facilities for instruction, and increased corps of teachers, it will meet with still greater success.

THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE.—At the annual meeting of the Board of Trustees of the New York Ophthalmic and Aural Institute, on Tuesday, 16th, the following officers were elected for the ensuing year: President, Frederick Swinton; Vice-Presidents, Drs. W. A. Draper and William A. Wheelock; Secretary, Eugene S. Ballin; Treasurer, Philip Bissinger. The treasurer reported \$15,412.28 receipts, and \$17,320.33 expenses, leaving a deficit for 1882 of \$1,908.05. The Medical Report shows that in the Dispensary 6,423, and in the Hospital 320, patients were treated, and that 550 operations were performed during the year. Of these operations, 97 were for cataract. In thirteen years there have been treated in this institution 63,789 patients, and 5,835 operations have been performed.

SUCCESSFUL TRANSPLANTATION OF MUSCLE.—Gluck (Berlin) has shown, by experiments upon animals, that muscular tissue can be successfully transplanted. In February last, Helferich (Munich) removed a tumor from the upper part of a man's arm, and in doing so had to remove nearly the whole thickness of the biceps muscle, to the extent of four and a half inches. To remedy this defect, he transplanted a slightly longer and thicker portion of the *biceps femoris* of a dog, securing it by catgut sutures at both ends. The operation was performed with strict antiseptic precautions, *minus* the spray. At the first dressing, ten days after the operation, it was found that a portion of the transplanted muscle, the full length of the original portion, but not an eighth part of its thickness, was "necrosed." After that the wound healed rapidly. The subsequent application of electricity restored the function of the arm, and it appeared to those who observed the case that the transplanted muscle contracted under its application. This case was reported at the German Surgical Congress in June last, and, in the discussion which followed, Lange (New York) stated that he also had transplanted a piece of dog's muscle to fill a defect caused by an operation, and that the graft had united, but showed no signs of functional activity.—*Beilage z. Central. f. Chir.*, 1882, No. 29, D. (*Glasgow Medical Journal*.)

PERFORATION OF THE INTESTINE BY ROUND WORMS ("Deutsch. Arch. f. klin. Med.," 29 B.).—Dr. E. Marcus reports the case of a thirteen-and-a-half-year girl, intellectually badly developed, an onanist, who sickened suddenly, with symptoms of vomiting and pain in the abdomen of such violent nature that she became mad, and could not be examined. On the next day there was well-marked, diffuse peritonitis, and six days later she died. At the autopsy, besides the diffuse purulent peritonitis, there were found (still living) in the pars descendens of the duodenum three large round worms. On the inner side of the intestine was a perforation six mm. long, the bloodless edges of which lay quite close upon one another. In the duodenum were four more worms. The deceased Professor Perls declared this case to be one of ascario-phagic perforation, the existence of which he had previously doubted. Leuckart, in his time, acknowledged without hesitation the possibility of such intestinal perforation, and veterinary surgeons have made observations of cases which can not be disputed.—*The American Journal of Obstetrics and Diseases of Women and Children*.

ARMY INTELLIGENCE.—*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 6, 1883, to January 13, 1883.*—SKINNER, JOHN O., Captain and Assistant Surgeon. Granted leave of absence for one month. Par. 2, S. O. 5, A. G. O., January 6, 1883. — WOOD, MARSHALL W., Captain and Assistant Surgeon. Granted leave of absence for one month. Par. 3, S. O. 4, Department of the East, January 8, 1883. — MUNDAY, BENJAMIN, First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Klamath, Oregon. Par. 3, S. O. 195, Department of the Columbia, December 29, 1882. — JOHNSON, R. W., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. Par. 2, S. O. 4, Department of Dakota, January 5, 1883.

Lectures and Addresses.

LECTURES ON HUMAN AUTOMATISM.

DELIVERED AT THE LOWELL INSTITUTE, BOSTON.

By WILLIAM B. CARPENTER, M.D., LL.D., F.R.S., ETC.

LECTURE II.

(Concluded from page 88.)

I pass from these to the animals of the *articulate* type, in which the segments of the body are arranged in longitudinal series, instead of round a center; and I take as an example of this type the *centipede*, in which the succession of segments making up the body is nearly uniform, every one having its pair of legs, while in the front is a head furnished with a pair of eyes, and with other organs of sense in relation with the mouth. The nervous centers are arranged in a similar series, each segment having its own ganglion in connection with its pair of legs; and the movements of these propel the animal, not in any direction, like the flapping movements of the *Medusa* or the swimming of the *Comatula*, but *forward*, or in the direction of the head, and which has within it a pair of large ganglia that are in direct connection with the eyes.

I must here stop to describe the difference between a nerve trunk and a ganglionic center. In the cases which I have already brought before you that distinction is not apparent, the whole of that peculiar modification of protoplasmic substance of which it is essentially composed seeming to possess a like power both of generating and of conducting what we call "nerve force." But we have now arrived at a grade of specialization in which the difference between the nerve fiber that conducts and the nerve center that generates the force is distinctly marked. That nerve center we call a *ganglion* (which comes down to us from the old Greek writers on medicine), the term ganglion merely meaning a knot upon a cord. And we have further to speak of what we term "reflex action"—namely, the physical action which takes place in those ganglionic centers, in response to impressions brought to them by *afferent* nerve fibers, which are (so to speak) reflected downward to the muscles by a distinct set of *motor* fibers. Now, we have a very good illustration of this kind of action in a curious animal with which some of you may be acquainted—the *Ascidia*, belonging to the lower type of aquatic mollusca—which has a complicated visceral apparatus inclosed in a firm membranous bag with two openings. Through one of these openings water is continually being drawn in, not by any muscular action of the bag itself, but by the agency of the cilia which clothe the whole of the respiratory surfaces in its interior, and keep up over them a constant flow of incoming water. Of the current thus produced, one portion passes on to the entrance of the stomach, which lies at the bottom of the bag; and, after passing through the alimentary canal, and yielding up any nutritive particles which the water may bring in, it meets the part which has passed over

the respiratory surfaces and aerated the blood; and the two united streams pass forth by the excurrent orifice. Now, the interior of this bag is crossed by muscular fibers in various directions, and the incurrent orifice is surrounded by what appear to be sensory tentacles. It is impossible to say what degree of consciousness this animal has; but I think it must possess some form of sensation. If any particle larger than usual comes against one of these tentacles, there is an immediate contraction of the muscular bag, and the particle is driven away by the ejection, from the orifice of entrance, of a jet, of water, which carries it off. Now, it will occur to you that this action is a sort of cough on the part of the animal, being exactly parallel to the act of coughing in ourselves, which I analyzed to you in the last lecture, and being executed by a respiratory ganglion which is situated between the two orifices. This ganglion, with the nerve fibers connected with it, seems to constitute the whole nervous system of the animal. One set of fibers (*afferent*) comes to it from the oral tentacles; another set (*motor*) proceeds from it, to be distributed to the muscular wall of the bag. The *neurosis* generated by the impression made upon the tentacles is conveyed by the *afferent* nerve fibers to the ganglionic center, and from that center a *neurosis* is "reflected" along the set of motor fibers which proceed to the muscles, calling forth their contraction.

Now, in the centipede we find each segment of the body possessing a ganglion of its own, connected by nerve fibers with the legs and their muscles; and as these segments closely resemble one another in their structure and actions, so also do their ganglionic centers, the only marked difference being in the two ganglia of the head which are connected with the eyes. Now, we will analyze the actions of this creature and see what conclusions we may draw from them. In the first place, every pair of legs is connected with the ganglion in its own segment by nerve trunks; and each of these, we have every reason to believe (Sir Charles Bell's researches having shown it to be the case in our own nerve trunks), contains both sets of nerve fibers—"afferent" fibers proceeding toward the ganglion from the sensory termination of the leg, and "motor" fibers proceeding from the ganglia to the muscles of the leg. Now, we often meet with these "hundred-legs" when we are digging in the ground, or see some other types of them in the midst of rotten wood. And you have, doubtless, seen that, if in digging you cut one of them across with your spade, both parts of the body will continue to run for some time. Now, as this movement must be maintained in the hinder part by the purely automatic action of its legs, every pair of them receiving its nervous supply from its own ganglion, the action of the legs in the fore part of the body may be fairly attributed to the like automatic mechanism, under the direction and control of the ganglia in the head. My late friend, Mr. Newport, the celebrated insect anatomist, made the following experiment upon one of the common small centipedes of our own country: He took out the gangliated cord from the middle segments of the body, without dividing the body itself, and found, as he expected, that while the legs of these segments were perfectly paralyzed,

the hinder legs were not paralyzed, but went on moving, as did the fore legs also, so that the body continued to move onward without the participation of the middle legs. But a very curious thing showed itself when he brought an obstacle in front of the animal that it could not get over; for while the front legs stopped—the animal being made aware of that obstacle by the visual impression transmitted to the optic ganglia, by which the actions of the ganglia of the front segments were controlled through the longitudinal cord of connection—the legs of the hinder part of the body went on moving, and pushed the body onward so that its front portion rose against the obstacle. This clearly depended on the continuance of the automatic action in the hind legs, which were removed from the control of the animal, the intermediate part of the longitudinal nerve cord having been cut away, while, on the other hand, the front legs were kept still by a similar automatism (I think we may believe) directed by the optic ganglia through which the animal was made conscious of the obstacle.

We may find in the actions of insects very clear exemplification of the same type of reflex action. Here is one which is known in France and in other countries by the term of the Praying Mantis—the *prie-Dieu* of the French—on account of the particular attitude in which it lies in wait for its prey—stretching out his first pair of legs, which act as arms, somewhat in the attitude of prayer. Here we have the head, then the first long segment of the body with its pair of predacious arms attached to it, and then the two other segments of the thorax, carrying the two pairs of wings, and the other two pairs of legs. Now, when any unlucky insect comes within reach, the mantis embraces it with these arms, forces its claws into its body, and soon devours it. Now, if the head of the mantis be cut off, the body will continue in the same position; and though it can not see when an insect comes near it, yet if an insect is brought within its claws, and is made to touch them, the arms will immediately contract and close around it; and if this segment of the body be separated from the rest, the arms can still be made to close, and will remain in the same condition for some time afterward. Further, when the rest of the body is still maintaining its position, supported by the two hinder pair of legs, and an attempt is made to overthrow it, the wings will immediately begin to be violently agitated. It is obvious, then, that all these are purely reflex actions, automatically sustained by the nerve centers, and not controlled by anything which we can call will on the part of the individual. They are types of pure physical automatism.

That a particular stimulus may be required to call forth a respondent movement is shown by the fact that, if a water-beetle called the *Dytiscus*, from the head of which the ganglionic centers have been removed, be placed upon a dry surface, it remains motionless, while, if cast into water, it executes the usual swimming movements with great energy and activity, though obviously destitute of any power of avoiding the obstacles of which, in its normal condition, it would be informed by its sense of sight.

Now, what actions of the like kind are performed by our

bodies? We find a parallel to them in a number of movements which show themselves in the very earliest stage of infancy, and which continue throughout our lives; and also in a number of morbid phenomena which occasionally present themselves in various combinations, and to which it will be useful to refer as additional illustrations of the same type of action.

Take, in the first instance, the act of sucking in the infant. The first thing the infant does when it comes into the world is to cry, and the next thing is to suck. The latter is effected by a combination of a number of separate muscular movements, all tending to the same action—the creation of a vacuum in the mouth; and when the milk flows into the mouth, to take the place of the vacuum, it is swallowed as fast as it is received, by another combination of muscular actions. Thus, in the act of sucking, two distinct groups of automatic movements are combined—that which is concerned in respiration, and that which is concerned in swallowing; and the combination is altogether an extremely complex one. Yet that combination is made, we are perfectly certain, quite independently of the cerebrum or brain proper, and by a purely automatic action of the lower nervous centers. Vertebrate animals have at the base of the skull, passing forward from the entrance of the spinal cord, a chain of ganglionic centers connected with the several organs of sense, behind which, just within the skull, and continuous with the spinal cord beneath, is a set of ganglionic masses which serve as the centers of the reflex actions of respiration and deglutition (swallowing). The cerebral hemispheres, on the other hand, are super-added organs, the size of which has no relation whatever to that of the other ganglia; and they seem to be in connection, not directly with the sensory and motor nerve trunks, but with the gangliated tract they overlie, in which these trunks have their proper centers. We find, in fact, that, the larger the cerebrum, the smaller are the other ganglia in proportion to it. In the fish, the brain consists almost exclusively of this series of ganglia, there being nothing that can be certainly called a cerebrum. But, in ascending through the class of reptiles to birds, we find the cerebrum progressively increasing in size, while still retaining a very simple type of structure. And as we pass from birds to mammals, and from the lower to the higher orders of the latter, we meet with a very marked increase, not only in the relative size, but in the complexity of the cerebrum, which increase seems to correspond with the predominance of the reasoning faculty (manifested in the *purposive* adaptation of means to ends) as a spring of action over irrational instinct. Now, it has been proved that the action of sucking in the infant is entirely independent of the cerebrum, for infants have been born without any cerebrum at all, and yet have lived, and sucked, and moved for some hours, or even days, afterward. And the experiment has been made of removing the cerebrum from new-born puppies, which have been found to suck just as well without the cerebrum as with it. Hence, it is clear that the action is purely automatic; and its "reflex" character is shown by the fact that it is excited in such cases by placing the finger moistened with milk in contact with the lips. Thus, the first action of our infancy—the one most

immediately necessary for the maintenance of physical life—is provided for entirely by this automatic mechanism. The same provision is made, as I pointed out to you in the previous lecture, in regard to the movements of respiration, which are sustained through the whole of life through the same apparatus, without any will or concern of ours, excepting that which we interpose for the purposes of speech, or for any experiment we may make upon our respiratory action. The normal rhythmical movement is sustained regularly and according to our requirements by the reflex action of the ganglionic centers that lie at the top of our spinal cord, just within the skull, the ordinary stimulus to that action being the presence of venous blood in the lungs, and this stimulus being augmented in force when imperfectly aerated blood is sent into the systemic circulation. So, again, the act of swallowing is in itself a purely reflex movement. You may be surprised when I say so, as you may think that you swallow by an effort of the will. What you really do is to carry, by the act of will, the substance to be swallowed within the reach of the real swallowing muscles, which then lay hold of it just as automatically as do the tentacles of a sea anemone, that lay hold of a small crab, or a bit of fish which you put within their reach, and carry it down into its stomach. Your own muscles of swallowing surround the funnel-shaped dilatation at the top of the gullet, into which the muscles of the mouth convey the food or drink to be sent down into the stomach; and these muscles are called into involuntary contraction by the impression thus made upon the lining membrane of the gullet—as is shown by an experiment you may try if you choose. If you pass a feather quickly backward and downward a little way down your own throat, or that of another person, you will find the feather laid hold of and drawn downward, so that, if it be not held firmly in the fingers of the person who introduces it, it will be taken out of them and carried down the gullet by the automatic action of its muscles. You know that when once the morsel has passed the “swallow” it is propelled downward into the stomach exclusively by the automatic movements of the muscles of the gullet, the will having no control over it, and no consciousness of its passage being excited, unless either its bulk or its temperature makes an unusual impression on the sensory nerves of the part. When the food reaches the stomach, you are aware that it is kept in a state of constant motion during the process of digestion—a motion of a very curious churning kind, kept up by the contractions of the muscular wall of the stomach, which (as it were) keep perpetually turning the mass within it inside out, so as constantly to bring the freshly introduced portions of the food to the exterior and subject them to the action of the gastric fluid secreted in the coat of the stomach, and which then carry them again toward the interior, and bring other portions to the outside. A remarkable evidence of this kind of movement is sometimes presented by the hair-balls that are found in the interior of the stomachs of oxen, these consisting of the hairs which have been licked away by the animals and have been carried into their stomachs; for these hair-balls are found to have the hair twisted and twined in the most remarkable manner, which can only be accounted for by this

peculiar, constant, restless, churning action of the stomach. No less automatic is the action of the two valves of the stomach, the one closing the termination of the gullet, so as (under ordinary circumstances) to prevent the regurgitation of the food, and the other at the pyloric orifice, which opens to allow the product of digestion to escape into the intestines. The action of these valves is altogether automatic; we have nothing to do with it, and, ordinarily, know nothing about it. When, however, the normal peristaltic movement of the stomach is reversed, as may occur to us in crossing the Atlantic, and the valve which guards the entrance of the œsophagus opens the wrong way, we do become unpleasantly conscious of what is passing within us; but this derangement of our automatism is altogether exceptional, the healthy man not being made aware, by any internal feeling even, that he has any stomach at all. The same may be said of the peristaltic action of the muscular wall of the intestinal canal, which automatically propels onward the contents of that canal until we again become conscious of their presence as they approach its outlet.

Take, again, the action of the heart, which is even more removed from our consciousness, excepting when it is disturbed by emotional influences, than even that of the stomach and intestines. This action goes on with perfect rhythmical regularity, accelerated under some conditions and decreased under others, through the whole course of our lives. Let that action be completely suspended even for a few minutes, and life entirely departs. In cases of longer apparent suspension, I believe that there is always a small, feeble action of the heart going on, for I do not think that without it life could be sustained at all.

Now, in all these cases you observe, then, that it is for the maintenance of the organic functions which supply the conditions for the exercise of the animal functions that this *primary or original* automatism is provided in the structure of our bodies. In the lower animals we have seen that the whole life of the creature is automatic, the movements of locomotion, as well as those connected with the organic functions, being thus provided for. But, in the case of man, the movements which make up his proper *animal* life have to be learned; and the mode of that training and acquirement will be the special subject of the next lecture. I think I shall then be able to show you that, when once learned, his habitual movements become as automatic in themselves as the movements of the lower animals, although they remain under the control of his will. We can set them going, and then leave them to themselves; but we can stop them whenever we please.

There is only one other point to which I shall direct your attention this evening—namely, that we have in ourselves actions of the same automatic character, which are connected with *sense-impressions* of which we are conscious, and which seem to me of the same kind as the visual automatism that obviously directs the movements of the centipede or mantis. The start at a loud sound, or the closing of the lids at a dash of light or at the sudden approach of an object, are actions as purely reflex as any of those that I have spoken of, though excited through a nerve center which does not seem to call them forth unless the conscious-

ness is excited. We require to *hear* the sound for the start to be produced; we require to *see* the flash of light for the sudden closure of the lids to take place. And I may illustrate this distinction by a very remarkable incident which happened some years ago to my late friend Sir Benjamin Brodie, the chemist, the son of the distinguished physiologist and surgeon, Sir Benjamin Brodie, a former President of the Royal Society. When Professor of Chemistry at Oxford, Sir Benjamin Brodie was experimenting upon a peculiarly explosive fluid of his own discovery, and was holding a small bottle of this fluid between his eyes and the light. Either through the tremulous motion or the warmth of his hand the fluid exploded with such violence as to blow to pieces—to dust, in fact—the bottle which contained it; and his first thought was, “I am blinded; this glass has been driven into my eyes, and I shall never see again!” Upon putting his hand to his eyes, however, he found that the glass had gone entirely into the *outside* of his lids, and that his eyes were perfectly safe. Either the flash of light or the explosion (which occurred first I do not know) had called forth an instantaneous respondent muscular movement, which protected his eyes by the closure of his eyelids.

Original Communications.

THE HISTORY OF ORTHOPÆDY.*

By LEWIS A. SAYRE, M. D.,

PROFESSOR OF ORTHOPÆDIC SURGERY AND CLINICAL SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE necessity of studying the treatment of deformities was admitted by the ancients, for we have from Hippocrates himself, who has been styled the “Father of Medicine,” a treatise “On Articulations,” in which he taught the proper method of bandaging, in cases of the infantile deformity of club-foot, which even in this day might be employed with advantage; for any theory of treatment founded upon correct ideas remains true forever. Celsus described the radical cure of hare-lip, and of various other congenital deformities, in a manner similar to that of the present day. As time went on, various persons attempted to ascertain the correct method of remedying deformities of the human frame. Empirics, and pretenders of all sorts, appeared from time to time, who professed to have discovered “the true secret,” and as there has always existed, and still exists, in the human mind, a disposition to admire the marvelous, and to be governed by decided assertion, without proper and careful investigation into facts, so men then became, as they now become, the dupes of the designing quack, who flourished and grew important through their weakness and credulity.

This tendency of human nature has shown itself, however, quite as much in other branches of the medical art as in that of orthopædy. Nothing can check this but the proper

education of the mind, whereby it is accustomed to examine and study into the *truth* of every proposition presented for its consideration.

Pretenders and quacks invariably publish accounts of their wonderful cures, and the miracles they have performed, in the secular press, or in other than scientific and professional journals, never laying down any laws or rules to aid another in performing the same cure in similar cases. And this constitutes one of the essential differences between an honorable physician and the quack. The one labors to disseminate and diffuse his knowledge for the benefit of his whole profession, in order that he may relieve as much of human suffering as is within his power; the other endeavors to conceal the little knowledge he may possess for his own particular profit or gain.

The importance of the subject no one can deny who pays the slightest attention to the numerous cases of malformation and deformity which we observe in every-day life. You can scarcely walk a block in this crowded city, or visit any of the smaller towns and villages of our wide-spread country, without seeing malformed or crippled sufferers, whose countenance bears the impress of mortified pride at their unfortunate condition, frequently connected with expressions of intense pain, produced by their abnormal physical position; hence the necessity of giving a special course of lectures on this particular department of surgery.

The etymology of the term has been in considerable doubt; Andry, of Paris, who has been generally regarded as the founder of this branch of surgery, derived it, to use his own words, “from *ὀρθός* which signifies *straight, free from deformity*; and *παῖδιον*, a *child*. Out of these two words I compound that of *orthopædia*, to express in one term the design I propose, which is to teach the different methods of preventing and correcting the deformities of children.”*

Other authors, however, derive the second part of the word, some from *παῖς*, a *child*, and others from *pes*, a *foot*; but both of these derivations seem inadequate to express the full sense of orthopædic surgery in the present day, limiting its extent as they do in one case to deformities of children, and in the other to those of the feet; whereas at the present time it extends not only to adults as well as children, but to deformities of all parts of the body. I would prefer, therefore, to derive the word from *ὀρθός*, *straight*, and *παιδεῖν*, *I educate*; this is more comprehensive, and embraces all deformities of the human frame, and also designates the principles of treatment. But as this would necessitate the coining of a new word to take the place of the one which has been recognized by general usage, I prefer to retain the term *orthopædia*, with the explanation above given.

The history of orthopædic surgery carries us back to an ancient date, and Holland seems to have been the birth-place of this branch of surgery. The first case of tenotomy for the removal of deformity is recorded by Tulpus, who mentions *Isacius Minius*, a Dutch surgeon, as having per-

* From the forthcoming second edition of Professor Sayre's “Lectures on Orthopædic Surgery and Diseases of the Joints,” New York: D. Appleton & Co.

* See “L'orthopédie, ou l'art de prévenir et de corriger dans les enfans les déformités du corps,” à Paris, 1741.

formed it in the year 1685, in the case of a boy, twelve years old, for the relief of *wry-neck*.*

Solingen also performed the same operation in the seventeenth century,† and Meeckren, Roonhuysen, and other Dutch surgeons, have left recorded cases; still, the great value of the operation had not been discovered or understood; for the great surgeon Boerhaave, and all medical writers of the former half of the eighteenth century, maintained the great sensibility of tendons and the grave danger in their section, so that we find *De la Sourdière* writes in 1742, as the closing words of a memoir, "The section of tendons ought, then, to be avoided."

Tenotomy consequently fell into disuse for nearly a century. In 1780 Andreas Venel, of Switzerland, established an institution in which he treated deformities of the human frame, club-foot, spinal curvature, etc. The first operation for the relief of club-foot by division of the tendo Achillis was performed by *Lorenz*, of Frankfort, at the request of *Thilenius*, on the 26th of March, 1782, in the case of a young woman, seventeen years old, by making a complete division of the soft parts, embracing the tendon from its anterior limits posteriorly. This allowed of an immediate descent of the os calcis to the extent of two inches, and in six weeks the wound was healed.‡

In 1803 Scarpa invented and made use of a shoe adapted to the bones of the distorted foot.

On November 16, 1809, Michaelis effected an imperfect section of the tendo Achillis.

Sartorius performed tenotomy on the son of Martin Oust, in May, 1812, with good result, but did not succeed in introducing the operation into Germany.

Tenotomy was not performed again till Delpsch operated by dividing the tendo Achillis in a child, six years of age, on the 9th of May, 1816,* by transfixing the leg in front of the tendon with a sharp-pointed bistoury, incising the skin to the extent of an inch on each side, and then dividing the tendon with a convex knife. The wound had not healed at the end of three months, and the result was only a partial success.‖

In 1822 and 1823 Dupuytren operated twice for wry-neck, and improved that operation as previously practiced.

The great discovery of *subcutaneous tenotomy* was, however, reserved for the genius of Louis Stromeyer, of Hanover, who first performed that operation in February, 1831,‡ and published his first six cases in 1834. Possessed of great talent, ardor, and energy, he caused his new principle to be generally known, and many great cures have since been effected by its application.

The names of Brückner, Camper, Wenzel, Palletta, Jackson, Sommering, Heine, and others, must not be forgotten, as each one assisted to develop scientific knowledge and

orthopædic surgery. Also, Dieffenbach, Langenbeck, and many others in Germany, accomplished much; while in France we find those of Bouvier, Bonnet, Guérin, Marjolin, Major, Delpsch, and Malgaigne, conspicuous.

In England, Dr. Little stands pre-eminent, having introduced orthopædy into that country. Having suffered himself from congenital club-foot, he knew how to estimate the relief afforded; and to his exertions and energy London owes the establishment of the Royal Orthopædic Hospital. Within the first ten years succeeding its establishment, *twelve thousand* patients were there treated, which alone is a proof of its necessity. Dr. Little's colleagues, Tamplin, Lonsdale, Broadhurst, and Adams, have also done good service in the cause of orthopædic surgery and science.

In our own country orthopædy met with very serious obstacles, the profession being seriously opposed to any innovation, and particularly to any subdivision of medical science into specialties. And many medical men of even great professional attainments, unwilling or unable to take the tedious trouble of attending to serious cases of deformity, would recommend such cases to various instrument-makers, in order to get rid of them; and these, mere mechanics, sustained by such recommendation, soon began to assume the name and responsibilities of "doctor," and would undertake the treatment of deformities, instead of adhering to their legitimate business, which was the manufacture of such instrumental aids as an intelligent surgeon might devise.

The injury thus inflicted on medical science and professional honor can only be properly appreciated by those who, like myself, have had frequent opportunities to witness its disastrous result.

Dr. David L. Rogers, of this city, was the first to perform tenotomy in this country; he divided the tendo Achillis in 1834, assisted by my colleague, Professor James R. Wood.

Dr. Richardson, of Kentucky, wrote an elaborate and instructive essay on the subject in 1838.

Dr. Detmold, who is now a Professor of Orthopædic Surgery in the College of Physicians and Surgeons in this city, a German himself, and who had enjoyed the advantages of Professor Stromeyer's instruction in Germany, introduced among us *subcutaneous myotomy* in 1837, three years subsequent to the introduction of tenotomy by Dr. Rogers, and made zealous efforts to render us conversant with its technicalities and therapeutic efficacy.

Dr. Valentine Mott, in his "Travels in the East and in Europe," published in 1842, expressed himself in the highest terms of admiration of orthopædic art, as he had seen it in Paris. It is but just to this distinguished surgeon that I should quote from his narrative, above referred to, in order to show how immeasurably he was in advance of the profession at that time. In fact, in his declining years, we here see abundant evidence that he was still entitled to the appellation of a *promoter*.

He says: "It was my happy lot, even at my advancing time of life, to have resided in this capital (Paris), and to have witnessed, also, the dawning, as well as the meridian splendor of another new and illustrious era in the healing

art; I refer to that beautiful and exact science, *limitedly* denominated *orthopædic surgery*.

"This great improvement, both in mechanical and operative surgery, is destined to be to the human frame what vaccination is and has been to the human features. As the discovery of Jenner has rid the world of a loathsome pestilence, and banished from our sight those disfigurements which made the most lovely lineaments and complexions hideous to behold, so will orthopædic surgery, by its magic touch, unbind the fettered limbs, restore symmetry to the distorted form, give mobility to the imprisoned tongue, and directness to the orb of vision.

"Like many other of the glorious achievements of surgery, it is based upon such simple and self-evident principles that it can not but be attractive, and carry home conviction to the plainest capacities. Its adoption must therefore be universal; and the more so, because liberally and extensively as the knife may be used, untwisting, as it literally does, the most misshapen and revolting and convoluted masses of deformity, by dividing deep, yet safely, under the skin, through the thickest and broadest muscles; yet are these operations, in many instances, almost *free from pain*, and without a *drop of blood*!

"And another remarkable feature, and one which gives the charm of magic to this truly brilliant triumph of our art, is the almost instantaneous restoration of every distorted part as soon as cut, and the righting of the limbs, the trunk and head, to their wonted beautiful symmetry and proportions, as the proud ship that has been bent down to the rude storm recovers her position, and resumes her stately course, when the shrouds have been cut away."

And further on he says: "Having myself pursued this new branch, as a student with my friend Guérin, for the last three years, and personally traced it through every step of its rapid progress from its birthday, I may say to its present perfect condition, I have thought that I could in no manner so well express my gratitude to him, to my country, and to my friends, for the kind feelings with which they have been pleased to cherish my name, as by attempting to found in this city of New York an American Orthopædic Institution, by which the principles and practice of that interesting science may be diffused far and wide through this my native land."

It was a great and melancholy misfortune, for our age and profession, that his career was so suddenly terminated; that thus the great desire of his life was not carried into practical execution.

Gentlemen, the ardent zeal with which this distinguished surgeon—the acknowledged head of his profession—devoted himself to the study of this new branch of the healing art is well worthy of your admiration and imitation. We here see one whose name was already recorded in the undying history of surgery on its very brightest pages, and who had already won its most brilliant and unfading laurels, applying himself for three long years as a student under the distinguished French surgeon, Jules Guérin, in order that he might become a perfect master of this new art. Strange to say, we find at the present day some young gentlemen complaining that three years is almost *too long* to obtain a

perfect knowledge of *all the different departments* of our profession. Yet a man who had devoted his life to this great work, who had more knowledge and reputation than almost any man our country has produced, and who had performed some of the most wonderful operations in the world, was thus willing to devote *three separate years* to this *one branch* of our profession.

You have in this fact exhibited one of the principal causes of this great man's most brilliant success. It was his constant and undeviating devotion to the study of his choice; his faithful application, and his unwearied toil, his determination to master all that genius had conceived, or industry developed, which was *new* in the profession of his adoption, which might add to its utility or give the power of relieving human beings in suffering and misery. It is an example worthy your imitation, and will lead any young man, who will make it his model, to ultimate success and honorable distinction.

Dr. Henry J. Bigelow, of Boston, published a work in 1845—it being a dissertation upon orthopædic surgery—which obtained the Boylston Prize for 1844, and was written on the following question: "In what Cases and to what Extent is the Division of Muscles, Tendons, or other Parts, proper for the Relief of Deformity or Lameness?" It was written after studying the works of Guérin, Bonnet, Velpeau, Phillips, Duval, and Little.

Since that time many gentlemen in different parts of the world have devoted special attention to this particular department of surgery; and many improvements have been made in the surgical treatment and mechanical devices for the purpose of relieving deformities of various parts of the body; still, at present orthopædic surgery is but imperfectly understood among us, and but few feel competent to practice it.

ON THE DIFFERENTIAL INDICATIONS FOR THE USE OF DYNAMIC AND FRANKLINIC, OR STATIC ELECTRICITY.*

By A. D. ROCKWELL, A. M., M. D.,

ELECTRO-THERAPEUTIST TO THE NEW YORK STATE WOMAN'S HOSPITAL, ETC.

ONE of the most difficult things in medicine is to correctly differentiate between the various remedies that may be suggested for a given disease.

I propose this evening very briefly to follow out this thought, so far as it relates to that much used, but much abused agent, electricity; for, now that it has in great measure been wrested from the hands of charlatans, it is in not a little danger of being wounded in the home of its friends. When a distinguished professor can say to a large class of students that a simple faradic apparatus will practically answer every purpose in medical electricity, it is in order still further to discuss the subject. Although well known that electricity is a generic term, including a wide variety of manifestations, yet in practice it is too apt to be forgotten. It should be remembered that when the statement is made that electricity has been used, it can convey but little to

* Read before the New York County Medical Society, January 22, 1883.

one's mind, unless the *kind* of electricity is mentioned, and, still further, the method of its application.

We have galvanic, faradic, and franklinic, or static electricity, each one of which differs from the others, both in its physical and physiological aspects, and necessarily in its therapeutical properties. Each one of these is effective also, according to the method of its application. Now, it is not to be supposed that one form of electricity is alone adapted to one line of diseases, a second to another, and a third to still another. There are indeed certain pathological conditions which always call for a certain kind of electricity, and, if benefit is to follow, it must come through this special form, all others being useless, or worse than useless. Let me specify one of the most familiar illustrations of this. In hemiplegia, where there exists, as is so often the case, an exalted electro-muscular contractility, electricity, if used at all, should be used in the form of faradization, and with an exceedingly mild and rapidly interrupted current. Under this treatment, improvement in the symptoms is not unfrequently accelerated, the paralyzed members becoming stronger, and the muscular contractions less readily produced.

Even when muscular contractions are *somewhat less* readily called out than in the normal condition, the same current is as a rule preferable.

On the contrary, when there is a very great diminution of electro-muscular contractility, the galvanic current is always indicated, the faradic coming into play only when the muscles give evidence of positive reaction to its influence. In most cases of paraplegia we generally find, after a short time, complete or approximate loss of farado-muscular contractility. The galvanic current is alone applicable in these cases, for the specific purpose of restoring nerve excitability, although the faradic may be useful in attempts to improve the impaired nutrition of the paralyzed members.

The difference in the reaction of the two currents is illustrated in an interesting manner in some cases of facial paralysis, and especially when it results from the action of cold (*rheumatismal*).

In these cases the faradic current does not cause contractions, while not only do the muscles respond to the galvanic, but a much weaker current will answer than when the parts are normal.

As the patient improves it takes an increased tension of galvanism to cause the same effects, until finally farado-muscular contractility becomes manifest.

Without specifying distinct pathological conditions, physical and physiological reasons render it evident that when we wish to directly affect the central nervous system the constant current is alone applicable. In the consideration of disease in general, however, the form of electricity to be used will depend very much upon the special manifestation of the symptoms and individual idiosyncrasies.

I may say that, in the majority of diseases where electricity is indicated, each one of its three forms—galvanism, faradism, and franklinism—may, at one time or another, possess a positive value over the others. This is illustrated in the condition that we term neuralgia. The well-known

power of the galvanic current to relieve many forms of pain has been repeatedly emphasized, while the efficacy of the faradic current in the same direction is seldom referred to; hence, the inference naturally is, that the latter for this purpose is of but little value. The truth is that faradism is not only invaluable in many forms of pain, but in certain conditions relieves, where galvanism is not only useless, but may even aggravate the symptoms. More specifically, the effects of pressure in the various forms of neuralgia are exceedingly useful as guiding symptoms, indicating the proper current.

I do not by any means lay it down as a universal law, but it will certainly be found that in the great majority of cases of neuralgia, where firm pressure over the affected nerves aggravates the pain, the galvanic current is indicated, while the faradic current has the greater power to relieve, when such pressure does not cause an increase of pain. In the class of cases called, sometimes, hysterical hyperæsthesia, it is well known that firm and prolonged pressure affords marked relief, while pressure superficially applied increases the distress. The faradic current is here infinitely superior to the galvanic.

It would, therefore, be untrue to say that galvanism is indicated for the relief of neuralgia, and that faradism is not. The measure of benefit to be obtained from one form or another depends upon the special characteristics of the case in hand. And yet, if it is impossible to point out many diseases where one current is to be used to the absolute exclusion of the other, it is possible to name a variety of conditions where, as a rule, one method of treatment, and one form of current, is superior to another.

In that class of cases that we sometimes speak of as general debility, if I may be allowed to use such a very vague specification, the faradic current is generally indicated. We select it because of its undoubted constitutional tonic effects. These tonic effects must come, in a measure at least, through the mechanical influences which agitate the superficial, and even the deeper seated nerve and muscular fiber.

The rapidly interrupted galvanic current possesses mechanical effects as great as, or even greater than, the faradic, but the difficulty with the former in using it for this purpose is, that the tension of the current must necessarily be so great as to produce reflex and direct effects, that might be in the highest degree damaging.

In order, however, to obtain satisfactory tonic effects from the use of faradization, very much depends upon the method of its application. It is essentially a method of detail. The method of general faradization,* to which I refer, where the whole body is brought thoroughly and completely under the influence of the faradic current, is in its relation to electro-therapeutics of the first importance.

It is many years since we described this method, and first enunciated the idea that electricity was not merely a stimulant and irritant, but a powerful tonic as well. This

* In my third revised edition of *Electricity in Medicine*, Macmillan and Surgical Electricity, 1882, the method of general faradization, and effects of general faradization are fully described. Wm. W. & Co., publishers.

theory excited at first not a little attention both at home and abroad, and especially in Germany, where it is still used with excellent effect by those who have become adequately skilled in its application. Nevertheless, it is even yet almost entirely ignored in this country in the writings and lectures of our prominent medical teachers.

The evidences, however, of carefully elaborated individual experiences have greatly multiplied during the past decade, and furnish abundant evidence of the correctness of this theory. Unfortunately, very few have undertaken to write upon this subject, and these individual experiences, so rich in results, and so important as evidences, are practically lost.

Concerning individual conditions that seem to demand the faradic current alone, there is not much to be said. There are in various generic diseases, if I may so speak, special symptoms that invariably demand one or the other of the two forms of dynamic electricity, and even special qualities of the same current. I have already alluded to this point in speaking of paralysis. But there are few distinct organic or functional diseases that in every phase of their manifestation demand alone and always a special form of electricity.

Asthenopia, a symptom depending on an absolute or relative deficiency of energy in the muscles of accommodation, and accompanied by hyperæsthesia of the retina and ciliary nerves, is one of the few distinct conditions that seem to demand the faradic current alone. I will not say that galvanism is never servicable, but my experience at least seems to teach that instances where faradism is not immeasurably superior to galvanism are so exceptional as practically to exclude the latter from consideration. The paralysis following diphtheria is another condition for which galvanism is of but little service, but where the proper use of faradization is often quite remarkable in its effects.

I have had in the various sequelæ of diphtheria an exceptional experience, which enables me to say that while the larger proportion of cases tend naturally toward recovery, yet the duration and force of the paralysis are greatly shortened and broken by electrical treatment. On the other hand, there are cases so obstinate in character that nature seems unequal to the task of relieving.

Some months ago I was called to West Milford, New Jersey, by Dr. Archer, of that place, to see with him the most severe and persistent case of diphtheritic paralysis that I had ever seen. The patient was a young married lady, aged twenty-five, and for three months the paralysis had persisted without abatement.

It was with difficulty that she could either swallow or speak; all four extremities were almost completely helpless, and associated with this were ptosis of the left eye and double vision. The patient improved immediately under faradization, and within three weeks was able to leave her bed.

In a case sent to me by Dr. J. D. Bryant, and now under treatment, where the pharyngeal muscles were badly paralyzed, six applications have restored approximately the lost power.

Among those diseases for which galvanism is, as a rule,

more servicable than faradism, there are a few where it is almost exclusively indicated. The so-called spinal irritation or spinal neuralgia is one of these. Under simple galvanization of the spine, aided sometimes by the tonic influence of general faradization, the tenderness to pressure over certain well-defined areas uniformly disappears.

Especially is galvanism of inestimable service in certain sequelæ of cerebro-spinal meningitis.

Following this terrible disease is a collection of the most distressing and persistent symptoms, which are yet perfectly curable. Some of the main symptoms consist of the severest pain, sometimes beginning in the eyes, and extending over the head to the neck and lower cervical vertebrae. Associated with this is a distressing stiffness of the muscles of the neck, with a constant drawing of the head backward. Occasionally no posture is endurable, excepting when the head is thrown far back, and in some of the worst cases I have known these muscular contractions to become convulsive. That unpromising and mysterious disease known as exophthalmic goitre is often much relieved and sometimes cured by electrical applications, but uniformly through the use of galvanism. The process of general faradization, through its powerful tonic effects, I have known to materially aid in the recovery, but galvanization must ever be the main reliance.

For the restoration of the lost senses of taste and smell, galvanism succeeds where faradism fails.

I may mention, also, that in most of those skin affections in which electricity has been shown to be of service, the galvanic current is vastly superior to the faradic.

In the pain of herpes zoster especially, galvanism is eminently efficacious, while in the field of electro-surgery it is supreme. In the treatment of erectile tumors especially, for which it is a specific, galvanism is used exclusively.

Some of you may not be aware of the remarkable results following the use of electricity in extra-uterine pregnancy. Both currents have been used successfully, but, to cause the speedy death of the fetus, my experience leads me greatly to prefer galvanism. Chorea, both acute and chronic, is a disease for which electricity is especially indicated. Both forms of dynamic (and even franklinic) electricity are of value, and, in any individual case, it is impossible, without careful examination, and sometimes tentative treatment, to differentiate between the two. In a case of this kind, and we frequently see such, where the appetite is good and even voracious, the nutrition unimpaired and the strength vigorous, the galvanic current, by the method of central galvanization, is almost invariably indicated; if, on the contrary, the patient is weak and anæmic, with nutrition generally impaired, thorough treatment by general faradization is always in order. In amenorrhœa the same principle generally holds good. If the patient is chlorotic and weak, faradization is the proper method, while the interrupted galvanic current, or the shock of franklinic electricity, is more frequently indicated when the suppression or retention are due to local rather than to constitutional causes.

The record, also, of electricity in dysmenorrhœa is brilliant. Both currents, either alone or in alternation, have proved efficacious, although the galvanic is most frequently

indicated. From franklinic electricity tonic and sedative effects of a very interesting and positive nature can be obtained, either by insulation by sparks or the use of the roller. Speaking from a considerable experience with this form of electricity, I should say that, while its constitutional tonic effects are unequal to those that follow general faradization, when this method is carried out properly, with due attention to detail, yet, as an adjunct or supplement, it is invaluable. It is one of the familiar things in medicine that a remedy which at first acts well may, after a time, prove inefficacious, rendering it necessary to resort to some other remedy of the same class. This is true in regard to the dynamic and static forms of electricity. Occasionally cases of nervous exhaustion, as well as other forms of disease, after improving to a certain point, under the influence of galvanism or faradism, hang fire, as it were, but by submitting the patient to the action of franklinization a new impulse seems to be given. In this way, one treatment supplementing and re-enforcing the others, results are obtained far more satisfactory than could possibly follow the exclusive use of general or localized faradization, central galvanization, or franklinization. Pain is sometimes relieved by franklinization after both galvanism and faradism have failed, but this is not the rule. The pain of muscular rheumatism, however, is relieved by this method sooner and more effectually than by the others. For this purpose, the treatment by the roller, which exercises a generally stimulating effect over a broad surface, is superior to the treatment by sparks.

In the various forms of true neuralgia, franklinism is not comparable in power to galvanism. The pain that the former is frequently so successful in subduing is generally of a chronic character, confined to no special nerve trunks, dull and aching in character, and with no tenderness on pressure. In these cases, I have long known that faradism was superior to galvanism, but more recent experience has convinced me that franklinization is more efficacious than either. In the enlarged joints of sub-acute and chronic rheumatism, and to excite the process of absorption in chronic synovitis, the treatment by sparks is frequently more efficacious than either faradization or galvanization. In old contractions, and in cutaneous anæsthesia, franklinization frequently possesses advantages over the others.

In electro-diagnosis, however, franklinic electricity is of but limited value, those qualitative and quantitative changes, which are so important as indicating structural degeneration, being satisfactorily indicated only through the action of the two forms of dynamic electricity.

Valuable as is franklinic electricity, it has a more limited range of usefulness than dynamic, and the more strongly this fact is impressed on the professional mind the better. He who begins with franklinism the study and practice of medical electricity, begins at the wrong end. Let him first master dynamic electricity, and then supplement his knowledge and experience in this direction by franklinism. The differential indications, then, for the use of galvanism, faradism, and franklinism, may well demand the closest scrutiny, for on the accuracy with which we estimate these indications will largely depend the success of our efforts. If

we do not clearly appreciate the difference in action and adaptation to symptoms of the different forms, we either fail to obtain results that are obtainable, or valuable time is lost in the change of treatment.

NASAL DIPHTHERIA.

BY THOMAS AMORY DE BLOIS, M.D., BOSTON.

LARYNGOLOGIST TO THE BOSTON HOSPITAL.

THE modes of invasion of diphtheria are so various, and the modifications of the disease so manifold, that, as Dr. Mackenzie remarks, "a diagnosis may be almost a matter of impossibility in those cases which differ from the normal type, in the direction either of unusual mildness or unusual severity."

However frequently this error in diagnosis may occur, where the disease first shows itself in the pharynx, when it invades the nasal passages, its recognition must certainly be much more difficult, for, although it is an easy matter to make a rhinoscopic examination in health, in disease such an exploration is many times next to impossible.

That there are often cases of nasal diphtheria which pass unnoticed must occur to any one who has witnessed the many ulcerations of the nasal mucous membrane of children occurring during the winter months, and which can not be accounted for on the score of either syphilis or catarrh.

By nasal diphtheria I do not wish to imply the spread of the diphtheritic membrane from the fauces to the nasal passages, an extension, as it were, of a process already existing, but a disease which makes the first manifestation of its presence in the nose, either posteriorly or anteriorly.

This affection ordinarily takes the form of catarrhal diphtheria, and in mild cases attracts but little attention except from the length of time that the trouble persists, and which is usually supposed by the parents to be a "bad cold."

The cases which ordinarily come under the notice of the physician, and those which attend our dispensary clinics, are the ones in which either the membrane presents itself to view at the anterior nares, or, after confining itself for some time to the nasal passages, subsequently invades the pharynx, larynx, and trachea, and there distinguishes itself from the ordinary sequence of diphtheritic cases by the severity of its course—as if, from the length of time that the poison had, unnoticed and unchecked, been retained in the system, that system had become the more thoroughly saturated by the infection which had advanced thus insidiously.

The patient—and it is usually a child, for children are generally the victims of this variety of diphtheria—shows very few of the prodromal symptoms of the disease. There is little or no malaise, and even with the appearance of the membrane there is only a very slight soreness of the throat. The glands of the neck are not enlarged, and little soreness of the fauces is manifest; if any, only the slight erythema accompanying the ordinary catarrhal sore throat.

The first indication is a snuffling at the nose, followed by a slight watery discharge, which is usually more or less purulent and often sanguineous, besides which it is frequently exceedingly offensive by its fetor.

On inspection, the fauces present a reddened appearance.

studded with spots of peculiarly white deposit, which are as intimately adherent to the mucous surface as the membrane found in other varieties of the disease; these spots gradually coalesce, and the patches progress until they reach the border of the skin, where they appear to become arrested by the denser tissue, and have the appearance of a complete investment of the nasal passages, bounded by a bright red line of demarkation and covered usually by a thin watery discharge. This membrane generally covers the entire posterior nares as well as what is in view anteriorly, although, from the difficulty of examination, it may escape recognition.

Besides these nasal and pharyngeal symptoms, there frequently supervenes a severe laryngeal affection, characterized by general difficulty of breathing and frequent attacks of severe dyspnea, which appear to be a laryngismus, for the larynx is always quite free from membrane, and the obstruction would appear to be from a spasm of the glottis.

In a large majority of nasal diphtheria cases, within a few days the disease will begin to retrograde, and the patient may get better without the deposit appearing at any other point, under which circumstances, after a day or so, it becomes loosened from one nostril and then from the other, and in the course of a week or ten days the patient is completely restored to health. Secondly, the disease may take on almost a chronic form, and the membrane remain adherent to the nostrils for many weeks without causing much inconvenience to the patient. Finally, in a few other cases, as has before been stated, the disease will pass downward, and the patient finally succumb to the later effects of what seemed at first to be a comparatively mild form of diphtheria.

As regards the sequelæ of this form of diphtheria, we miss that occasionally found with other forms of the disease—laryngeal paralysis. It never follows, and usually, if we do not include some slight ulcerations of the anterior nares, there are no unpleasant after-effects of the malady, with the exception of paralysis of the velum palati, which occasionally supervenes as in other forms. I have never seen a case of this, but Dr. Carl Seiler, of Philadelphia, states that out of several cases of nasal diphtheria seen by him, and which all terminated favorably, two subsequently had paralysis of the soft palate.

CASE I.—Edward H., aged five years, a patient of the Boston Dispensary, appeared with his mother in September, 1882. The mother stated that she believed the child to be perfectly well, with the exception of a persistent cold in the head, which she stated had lasted for about two weeks, the little one playing about the house and seeming as well as usual. The patient appeared to be a healthy, well-grown child, for his age; seemed in good spirits; no exacerbation of temperature or pulse. On examination of the nose, at both orifices appeared a dense white membrane which reached as far as the skin of the nose, from which it was separated by a fine red line. This membrane was somewhat raised above the surrounding surface, and was covered by a thin, white, watery mucus, rusty at some points, which trickled down on the lip, where it appeared to be the cause of numerous excoriations. The fætor of the child's breath was much greater than the amount of diseased surface would seem to account for.

Upon introducing a speculum, the membrane appeared to extend posteriorly as far as could be seen, and to completely invest both nostrils. Posteriorly, it was much the same; the vault of the pharynx and turbinated bones were almost covered with the membrane. Upon trying to detach a portion of this membrane in the anterior nares, a raw, bleeding surface was left, and it was impossible with the cotton stick to sweep away any portion of it.

There was no membrane in either the larynx or pharynx. It was difficult to make the mother of this little patient comprehend the gravity of the case, for, as she said, the child seemed perfectly well.

In regard to the treatment, the nostrils were sprayed out with a carbolyzed solution, after which iodoform was insufflated, and a stimulating and tonic medication ordered.

The case now passed into the hands of the attendant physician, who stated that he saw the patient next day, at which time the membrane had spread to the pharynx as far as he could see without the glass. The next morning breathing was impeded, and he advised tracheotomy, which was refused, and the little one died that afternoon, about forty-eight hours after the first examination.

CASE II.—Charles M., aged four years, a well-nourished child, who had always been well—in fact, this was the first instance of his having been under a physician's care—was taken sick about November 1st, the first symptom noticed by the parents being a very offensive puro-sanguinolent discharge from the anterior nares. On examination, there appeared a membrane in both nostrils, the edges of which were clearly defined, as they extended well to the front, and were terminated by a bright red line of demarkation. There was no fever. The pulse was soft and compressible. There was great loss of appetite and some loss of flesh. Although the child played about the house as usual during the day, yet at night he would be awakened by attacks of dyspnea, which persisted until a hot, moist sponge had been held over his mouth for a short while, when the dyspnea would disappear and he would fall asleep again.

In about three weeks and a half the membrane lining the right nostril became partially detached, though it was firmly adherent anteriorly, and could be heard flapping in the air-passage. Shortly after this it came away, the pus and blood stopped flowing, and that nostril became perfectly clear. In about a week more the second nostril cleared itself in the same way, and the disease terminated, without sequelæ, in about five weeks from its commencement. The treatment in this case consisted in washing out the nares frequently with a two-and-a-half-per-cent. solution of the sulpho-carbolate of zinc, the insufflation of iodoform, and the internal administration of brandy, milk, and beef-juice at short intervals.

CASE III.—This was the case of an adult, a wool-sorter by trade, by name John H., and aged forty years. He came under observation on the 23d of last March, and gave the following history: Two days before, in the afternoon, he was seized with a slight indisposition, and at the same time noticed that his neck appeared to be stiff, and that it pained him to swallow his saliva. However, he went on with his work, believing that he had a cold and that it would pass off.

It did not, however, and on the following day he noticed that he had great difficulty in breathing through his nose; but it was the pain in the neck which gave him most distress, and caused him to send for a physician.

When seen, he appeared to be a strong, robust man, evidently in good general health. On examination, there appeared a continuous lining of diphtheritic membrane, extending from the orifices of the nostrils as far back as could be seen, and it was extremely dense and thick. Posteriorly, it did not extend farther than the vault of the pharynx. There was no membrane in either the pharynx or larynx. This continuous lining was bathed in a thin, watery discharge, and the fetor was simply intolerable. There was no interference with respiration; the febrile symptoms were very slight. The neck was a good deal swollen, and appeared to cause him a great deal of pain. The patient was seen again that same evening. He certainly was much worse; the malaise had increased, and he was evidently in a very low state. On the following morning he began to sink rapidly, and died that evening, presumably from blood poisoning, thirty-six hours after first being seen.

Dr. S. W. Langmaid, of Boston, reported in the "Boston Medical and Surgical Journal" (vol. civ, No. 12) the following case: The case of a lady whom he was called to see, with symptoms of swelling and some pain in the throat, but no fever. On examination, he found a white membrane hanging down behind the soft palate, and, on using the mirror, he discovered that the whole surface of the right posterior nasal fossa was covered with a membrane which could not be detached by traction, and could not have been discovered without rhinoscopic examination, as it was localized there, not being present elsewhere. Simple syringing with permanganate of potash was employed, and the whole thing disappeared in three days. He supposed it was a diphtheritic membrane.

These few cases here cited are sufficient to show, at least, the diversity of the disease, for no two of them are alike. They vary from an attack which almost escapes detection by its mildness to one which overwhelms by its severity in the short space of three days. They are only similar in the fact that in all of them the disease was principally located in the nose before having appeared in any other situation.

While this peculiarity of location is not sufficient to call for a separate classification, yet the number of cases reported is so small, and they are so sparingly touched upon in works on diseases of the throat, that the subject must be one of interest to many.

One point, at least, most writers on the subject agree upon, and that is, that when the membrane involves the nasal passages it greatly increases the gravity of the disease. There are some cases that are very light in their character, and doubtless many others which escape notice altogether.

3 PARK SQUARE, BOSTON, January 5, 1883.

THE NEW YORK SOCIETY OF MEDICAL JURISPRUDENCE.—A SOCIETY has recently been organized under this name, and the following officers have been chosen: President, Mr. George P. Avery; Vice-President, Dr. J. S. Wight; Secretary, Dr. N. E. Brill; Financial Secretary, Dr. S. B. Livingstone; Corresponding Secretary, Dr. J. F. Chauveau; Treasurer, Dr. E. C. Harwood.

A CASE OF CAUSALGIA.

By CHARLES T. POORE, M. D.,

SURGEON TO ST. MARY'S LANE HOSPITAL FOR CHILDREN.

IN April, 1882, I was asked to see Mrs. X. for a painful affection of the foot, following a fracture of the lower ends of the bones of the leg. The history of the case was as follows: In August previous, while standing on some steps, she fell, turning her right foot inward, causing, it was said, a fracture of the end of the tibia and a laceration of the external ligaments of the ankle joint. The parts about the joint immediately became greatly swollen and very painful. The limb was put up in a plaster-of-Paris bandage. After four weeks it was removed, and she was told to use the foot as much as she was able. Some weeks later she began to experience an uncomfortable burning sensation in the sole of the foot after walking, which gradually increased in severity until it assumed a very painful character. At the time of my visit she describes the pain as follows: After walking a short distance, or letting her foot hang down with a boot on, the sole of the foot, at a point corresponding to the metatarsophalangeal joints and a little behind them, began to burn, soon the skin became very sensitive, red, swollen, and the pain excruciating, so that she had to remove her boot; she had noticed that at times the skin had a glazed appearance. During the paroxysm the pain extended up on to the side of the foot, and then to the leg. When the pain was intense, she obtained relief by placing the foot in as hot water as could be borne. She had no pain when the foot was raised, even if she had a boot on. After an attack, the pain gradually diminished, and in an hour or so it disappeared. She had worn an ankle brace, but without deriving any benefit from it. There had never been any eruption on the sole of the foot.

On examination, the muscles on the posterior aspect of the leg are slightly shortened, so that the foot can not be flexed beyond a right angle with the leg without the use of considerable force. The leg is slightly oedematous. There is no pain on passive motion; the soft tissues over the right ankle joint are swollen. On the outer aspect of the foot, just anterior and below the end of the fibula, is a swelling, feeling like an enlarged bursa. On deep pressure in this location, there is some tenderness. The posterior tibial nerve behind the ankle joint seems slightly tender on pressure, but the examination does not give rise to any painful sensation on the sole of the foot. There is no pain or tenderness in the metatarsophalangeal joints, in the bones of the foot, nor in the soft parts at the time of examination, which was not during a paroxysm. There is some complaint at times of aching on the external border of the foot. The tarsal arch is somewhat flattened. The affected area corresponded to the parts under the metatarsophalangeal joints of the second, third, fourth, and fifth toes.

At the request of the patient, a trial of electricity was made; but, after a month's treatment, there was no diminution in the amount of pain nor length of the paroxysms. It seemed to me that nothing short of blistering or superficial cauterization would be of any benefit. I therefore asked that Dr. J. C. Harrison, of Brooklyn, should see the

case with me, which he did on the 17th of May. He agreed as to the diagnosis, and the advisability of using the cautery to the sole of the foot. A Paquelin's cautery raised to a white heat was applied to the painful point. The patient complained of but slight pain from the application, and was out in the afternoon. From this date until the 1st of June I cauterized the foot five times, with the result of an almost entire relief from pain. As she went out of town at this date, treatment ceased. She is now free from all trouble, and goes about as well as ever.

Remarks.—The main points in this case are: an injury to the ankle joint, from which there was a perfect recovery, as far as the bone lesion was concerned; a probable injury to the posterior tibial nerve, followed by a peculiar affection of some of its terminal ends of many months' duration; permanent relief after superficial cauterization, with a Paquelin's cautery applied five times, at an interval of about three days. The only account of this affection that I am aware of is in Mitchell, "On Injuries of Nerves" (Philadelphia, 1872), in which he states "that irritation of a nerve at the point of wound (injury) may give rise to changes in the circulation and nutrition of parts in its distribution, and that these alterations may of themselves be of a painful nature." "If the burning were a referred sensation, it would sometimes be met with in cases of complete division of nerves, and, therefore, in parts devoid of tactile sensation. But we have encountered no such case. . . . The agents which help these cases of burning are those addressed to the spot where the pain is felt, and *not* to the cicatrix."

The use of tincture of iodine applied over the ankle joint had failed to afford any relief. Cauterization at no time caused any abrasion of the skin covering the sole of the foot, nor was she prevented from walking. I found that, on account of the thickness of the skin on the sole of the foot, I had to pass the cautery more slowly than is usual in superficial cauterization of other parts.

Clinical Reports.

MOUNT SINAI HOSPITAL.

(Service of Dr. HENRY N. HEINEMAN.)

PERITYPHLITIC ABSCESS.

This patient was about thirty-five years of age. He was a hard drinker, and had had morning sickness for some time, and one or two attacks of jaundice. For two weeks previous to his admission to the hospital he had had irregular chilly sensations and febrile movement, and had been a part of the time in bed. He suffered from constipation and diarrhoea alternately.

On admission, the patient's temperature was 104° F. He complained of marked pain in the right lumbar and iliac regions and over the abdomen. There were swelling, dullness on percussion, and localized pain over the right iliac fossa. The diagnosis of perityphlitis was made.

His temperature reached 103° 5' for many days. After the administration of antipyretics, it was reduced to 100° 5', at which it remained for some time. Thirty grains (2·00) of quinine sulphate were given once or twice a day, and six minims (0·40) of

Magendie's solution injected thrice daily under the skin. Ice bags were applied locally, and the patient's strength was sustained with whisky.

Within a week after admission, well-marked signs of exudation about the cæcum were recognized, though no redness or œdema of the integument appeared. There were no signs of the pointing of an abscess.

Gradually the swelling decreased, the local tenderness diminished, tympanitic resonance was heard all over the cæcum, and finally only a slight fullness in the lumbar region posteriorly remained. The temperature had become normal, but the patient still seemed far from convalescence.

During the ninth week of his illness the evening temperature began to rise, and was uninfluenced by antipyretics. The patient became somewhat delirious. No satisfactory explanation could be found. In the tenth week the delirium continued, the pulse grew feeble, and the fever rose to 103° 5'. One morning he passed a chocolate-colored stool. The same afternoon his temperature rose to 104° 8', then to 106° 2', and he died in collapse—it was supposed either from perforation or from intestinal hæmorrhage.

An autopsy was held the next day. A large pus-cavity was found behind the cæcum, extending in a downward direction principally, as far as the ilio-pectineal line, infiltrating the iliacus muscle, and almost baring the ilium itself. Sinuses led upward behind the right kidney. The cavity was filled with a mixture of pus and recently effused blood, the latter about three fourths of a pint (thirty-five centilitres) in quantity. The large intestine also contained clotted blood. A perforation at the seat of an extensive ulcer just behind the Bauhinian valve communicated with the abscess cavity, and was the cause of the hæmorrhage.

RECTAL FEEDING.

Two patients have been sustained for three weeks by food given by enema. The rectum was first syringed and washed out with warm water. The following mixture was then injected: Milk, \bar{z} iv (128·00); whisky, \bar{z} ss. (16·00); pep-in, gr. xv (1·00); tr. opii, \bar{m} v (0·33), to be repeated after two hours.

The rectum was generally cleansed before each injection of aliment, though sometimes the patient retained two or three injections without a repetition of the irrigation.

RHEUMATIC PERICARDITIS.

A man, twenty-one years of age, was admitted November 20, 1882.

Previous History.—During the last two or three years this man has had occasional palpitation of the heart, but it has not inconvenienced him to any extent. A year ago last summer he lay in the open air, caught cold, and had rheumatism for a week. After this he experienced severer palpitation than before, and had some shortness of breath on exertion. Otherwise he was quite well, and could work hard without tiring.

A month ago he began to complain of pain in the back. Being a porter at the time, he laid it to overwork. He also had a severe naso-pharyngeal catarrh, with frontal headache, blood-stained expectoration, and epistaxis. He had pain in the precordia and left shoulder, fever, and general sweating. The joints were not affected. He received medical aid, and in two weeks felt comparatively well. About a week ago he had a slight chill, followed by fever and profuse perspiration. From this date he grew worse. The pain in the back and limbs and general stiffness returned, and the sharp pains in the chest. His inspirations were shallow and frequent.

On Admission, November 20, 1882.—The patient complains greatly of weakness; his appetite is poor; his tongue very much coated with a white fur; his bowels are constipated; his tempera-

ture is 101.3°, respiration 24, pulse 112, short, but rather full. His face wears an anxious expression, but is not cyanotic.

Physical Examination.—A peculiar "wavy impulse" at and above the apex of the heart can be seen and felt in the chest wall. The precordial flatness is of about twice the normal measurements, but does not extend to the right of the sternum. There is a very loud friction-sound synchronous with the first sound of the heart, and a short diastolic friction-sound. These sounds are best heard around the point at which the apex beats, and stop short at the left limit of the pericardium. A soft murmur is audible to the left of this and at the left side of the spine, with the systole. The cardiac impulse is very forcible, and the heart is probably hypertrophied.

The other organs give negative signs.

November 23d.—10 A. M., pulse 132, respiration 44, temperature 102°; 7 P. M., pulse 130, respiration 46, temperature 103°.

November 25th.—8 A. M., pulse 112, respiration 32, temperature 99.4°; 7 P. M., pulse 130, respiration 44, temperature 100.6°. A double friction-sound can be heard by applying the ear to the chest at the left side of the sternum. The ear serves better than the stethoscope. A thrill is felt at this point with the systole. The friction-sound is not so distinct at the apex as before. The area of flatness is in the form of a triangle, with the base downward, and extends from the second to the fifth interspace, and from the middle of the sternum one inch beyond the nipple.

November 28th.—8 A. M., pulse 84, respiration 36, temperature 99.2°; 5 P. M., pulse 100, respiration 32, temperature 100°. The patient feels very well, though still lying down. The circulation is good. He has some pain in the precordia. That at the apex is gone.

November 30th.—8 A. M., pulse 104, respiration 32, temperature 100.2°; 7 P. M., pulse 110, respiration 52, temperature 101.5°. More fever.

December 3d.—8 A. M., pulse 108, respiration 36, temperature 100°; 4 P. M., pulse 120, respiration 40, temperature 101.2°.

December 6th.—8 A. M., pulse 112, respiration 48, temperature 100.8°; 4.30 P. M., pulse 104, respiration 24, temperature 99.6°.

January 9, 1883.—For a month the patient has been gaining ground pretty steadily. He sits up every day, and is doing well.

Treatment.—The patient has received, from his entrance into the hospital, infusion of digitalis, $\frac{3}{4}$ ss. (16.00), with tincture of opium, \mathfrak{m} xx (1.33), every three or four hours. His strength has been kept up by whisky, $\mathfrak{f}\mathfrak{z}$ viij (25 centilitres) in twenty-four hours. Lately one half of this has been replaced by wine. During the exacerbation, about the 1st of December, he was given quinquina, gr. xx (1.33), twice a day. His dyspnoea has been relieved by inhalations of oxygen, three, two, and one a day. He is now taking wine, whisky, digitalis, and a little lactate of iron.

Book Notices.

The Physician Himself, and What he should Add to the Strictly Scientific. By D. W. CATHELL, M. D., late Professor of Pathology in the College of Physicians and Surgeons of Baltimore, etc. Baltimore: Cushings & Bailey, 1882. Pp. 194.

This book contains a curious medley of matter. Together with some bits of real information, such as it would be a task to collect from formal treatises, it gives a good deal of matter

that is not one whit higher than that of such trash as "How to Behave," "The Manners of Good Society," "The Complete Letter-Writer," etc. It is written in a style somewhat Tupperian.

The Spinal Nerves. By A. H. P. LEUP, M. D. Brooklyn: F. B. O'Connor, Jr. Pamphlet and folding plates. [Price, \$1.]

This pamphlet, with the number of loose sheets which accompany it, has caused the reviewer some surprise. Not that the tables printed upon the separate sheets are incorrect, or that the body of the pamphlet is inaccurate, although the latter is superficial and often disfigured by the use of capitals in the text; but because, while the author's copyright is prominently and repeatedly set forth, we find it to differ only in minor matters from other works already well known. We are particularly reminded of Flower's "Diagrams of the Nerves," and of certain of the tables given in Darling and Ranney's "Essentials of Anatomy."

BOOKS AND PAMPHLETS RECEIVED.

A Text-Book of the Diseases of the Ear and Adjacent Organs. By Dr. Adam Politzer, Imperial-Royal Professor of Aural Therapeutics in the University of Vienna, etc. Translated and Edited by James Patterson Cassells, M. D., M. R. C. S. Eng., Aural Surgeon to, and Lecturer on Aural Surgery at, the Glasgow Hospital and Dispensary for Diseases of the Ear. With 257 original illustrations. Philadelphia: Henry C. Lea's Son & Co., 1883. Pp. xii+800.

Legal Medicine. By Charles Meymott Tidy, M. B., F. C. S., Master of Surgery; Professor of Chemistry and of Forensic Medicine and Public Health at the London Hospital, etc. New York: William Wood & Co. Two vols. Pp. xxi+314; xi+298. [Wood's Library of Standard Medical Authors.]

On Slight Ailments: their Nature and Treatment. By Lionel S. Beale, M. B., F. R. S., F. R. C. P., Professor of the Principles and Practice of Medicine in King's College, London, etc. Second edition, enlarged and illustrated. Philadelphia: P. Blakiston, Son & Co., 1882. Pp. 283.

A Guide to the Practical Examination of Urine. For the use of Students and Physicians. By James Tyson, M. D., Professor of General Pathology and Morbid Anatomy in the University of Pennsylvania. Fourth edition, revised and corrected. With colored plates and wood engravings. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. 196.

The Harveian Oration, 1880. Delivered June 25th. By John W. Ogle, M. A., M. D. Oxon., F. R. C. P., Consulting Physician to St. George's Hospital. With additional notes and an appendix. London, 1881. Pp. 209.

Electricity in Medicine and Surgery. By George C. Pitzer, M. D., Professor of the Theory and Practice of Medicine in the American Medical College of St. Louis. St. Louis, 1883. Pp. 88. [Price, \$1.]

The Laws of Life, and their Relation to Diseases of the Skin. By J. L. Milton, Senior Surgeon to, and Lecturer at, St. John's Hospital for Diseases of the Skin. London: Chatto & Windus, 1882. Pp. 144. [Price, 3s.]

The Law of Human Increase. By Nathan Allen, M. D., LL. D. Pp. 10. [Reprint from the "Popular Science Monthly."]

Contributions from the Chemical Laboratory of the University of Michigan. Edited by Albert B. Prescott, M. D., F. C. S., and Victor C. Vaughan, M. D., Ph. D. Vol. I, part 1. Pp. 55. [Reprint from the "Physician and Surgeon." Price, 50 cents.]

Massage, its Modes of Application, and its Effects. By Dr. Douglas Graham, Boston. Pp. 74 to 137, inclusive. [Reprint from the "Popular Science Monthly."]

THE
NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 3, 1883.

THE PROBLEM AT ALBANY.

DURING the coming week the Medical Society of the State of New York will be called upon to take action with regard to a matter that has become of the greatest importance—not so much intrinsically as by reason of the side issues with which it has been tangled. We refer to the question of the code of ethics.

There are many in the profession who do not think it necessary that we should have any code at all. This journal is of that opinion, and, consequently, it expressed a qualified approval of the new code on its adoption, a year ago, for that code seemed a step toward the abolition of all codes, inasmuch as it nullified the most important element in the code of the American Medical Association, and, therefore, came as near being no code at all as could well be expected of a body that had just declined to commit itself to the no-code policy. That was our sole reason for approving of the new code, and we know of no reason to doubt that it was the feeling that actuated the promoters of the measure, notwithstanding the insinuations that have been published as to motives of self-interest on the part of that section of the profession.

Since the new code was adopted, it has been made the subject of comment by almost every medical journal, and by almost every public medical society in the country, and these comments, being almost invariably denunciatory of the action of our State society, have given abundant evidence that the greater part of the profession not only disapprove of that action, but feel outraged by it. This feeling is deep and genuine, and calls for the most deferential consideration, whatever we may think of the way in which it has been expressed. We therefore trust that at the coming meeting of the State society those who take part in the proceedings will sink any sense they may entertain of having been unworthily dealt with in the discussions to which we have alluded, and take up the problem before them with a firm determination to get at the real interest of the profession in general, and to work in favor of whatever settlement of the question may seem, after the fullest possible deliberation, best calculated to uphold that interest.

It will be no easy matter, we admit, for those who represent this city to lose sight of the indignities to which they have been subjected. They will find it difficult not to swerve under the galling and most unjustifiable imputation that they took the course they did a year ago because of a sordid longing for the means of enriching themselves by fees for consultations with practitioners of other schools than their own; under the palpable lie that they sprung the measure upon a small meeting, and carried it through to adoption by unbecoming tactics; under

the slanderous statement that they even go to this meeting pledged against any recession from their former position. Hard as it will be, however, to lay aside that bias that springs so readily from indignation and a sense of having been wronged, it must be done, and we do not doubt that it will be done. We do not doubt, and we earnestly hope, that those who question the wisdom of the old code will not only accord all due consideration to the sentiment evidently entertained by a large portion of the profession, but also yield something of their own convictions to the policy of conciliation and harmony, leaving the future to deal with the matter from the point of view of any change that may hereafter come over the feelings of the profession at large in regard to it.

While we believe that considerations like the foregoing will prevail, and while we urge that they should prevail, we deem it no more than just that those who have heretofore supported the new code should be set right before their fellows as regards their real motives. It is utterly absurd to say that they desire consultations with homœopaths, for instance. The incongruity of such consultations, if we use the term with any approach to its strict meaning, is obvious to all thinking men. The homœopaths themselves see it, if we may judge from the general tone of their journals; indeed, they have joined in the senseless cry that New York specialists are bidding for their practice, and declare that they will have nothing to do with us. As a matter of fact, the permissive clause has been in operation for a year, and yet we are unaware that a single consultation has been held under it that would not have been held without it. No, the accusation that any such sinister motive underlay the movement that ended in the adoption of the present code is as baseless as it is insolent. What the upholders of that code really did aim at was, so far as we are able to judge, to free the medical profession from the burden of a law that, while it restrained no knave, but only a few fools, from taking money in return for a ridiculous show of services to patients, yet seemed to the laity as odious as the Inquisition, and often served as a cover under which designing men persecuted those whom they disliked.

Away, then, with all the rubbish with which meddlers have clothed the question, and let us meet it squarely but temperately, to the end that the real interests of the profession in general may be served, regardless of the political whip on the one hand and of the weakness inseparable from personal feeling on the other hand.

DR. SQUIBB ON THE CODE QUESTION.

SINCE the preceding article was written, our attention has been called to a noteworthy paper on the subject, in the January number of the "Ephemeris of Materia Medica," etc., presumably by the senior editor of that journal, Dr. Edward R. Squibb, whose writings are always temperate and logical, and, therefore, justly call for the greatest deference. Dr. Squibb's devotion to the interests of the profession, and his knowledge of what those interests involve, are not exceeded by those of any other man. Such being the case, the fact that Dr. Squibb

has ceased to be a practitioner of medicine detracts not at all from the force of what he says.

Notwithstanding the ardor with which he advocates a return to the old code, his sense of justice and his regard for truthfulness, it is gratifying to observe, lead him to the express declaration that the aspersions cast upon the motives of the new-code party by all others who have opposed them publicly are unfounded. He charitably attributes those aspersions to the difficulty which the upholders of the old code must have found, he thinks, in conceiving of any creditable reasons that could have led men to such a revolutionary course as the substitution of the new code for the old. We have given certain reasons, and, whatever may be thought of their force, they certainly can not with any fairness be characterized as sinister or discreditable. We have no reason to suspect that the committee were actuated by any hidden motives, and it has seemed to us indecorous that others should have made insinuations to that effect almost their sole argument.

Dr. Squibb discerns that the new code abrogates the old one only in so far as it allows of so-called consultations with practitioners of those sects in medicine that are not represented in the State society. That is unquestionably true, and it strikes us as unfortunate that this should be the only marked difference between the two codes, for the idea of heterogeneous consultations is so absurd that the mere liberty to take part in them seems naturally, to most physicians, a lowering of the dignity of the profession to which they belong. Dr. Squibb consequently infers—and we sincerely trust that he may prove to be correct—that the new code will not satisfy even its promoters, and that the real question at issue is, a code or no code. Proceeding on this assumption, he argues ably in favor of the desirability of a code, stating, quite correctly, that some accountability on the part of individuals to an organization should be enforced. He seems, however, to overlook the fact that no right-minded man questions the need of such an accountability, as was exemplified in Dr. Roosa's resolution, which provided for discipline in cases of conduct unbecoming a physician and a gentleman—the precise counterpart of the army rule under which severe punishment is visited upon those convicted of conduct unbecoming an officer and a gentleman; a rule which, it is safe to say, has done far more to preserve the *esprit du corps* of our army officers than the Articles of War or all the specific regulations that could possibly have been devised. Moreover, he fails to consider certain experience that has been had in the working of the no-code principle; witness, Dr. Holt's account, alluded to in our last issue, of its operation in New Orleans for the last nine years; also the fact, open to every one's observation, that those of us here in New York who have been falsely accused of a longing for so-called consultations with practitioners holding tenets irreconcilable with our own, or practicing under what we look upon as false pretenses, have not yielded up our consciences to the license allowed by the new code.

Convinced that a code is necessary, Dr. Squibb sees nothing objectionable in the old code. As we have said in the past, we

look upon it as a monstrous inconsistency that a physician should be debarred from holding a patent while at the same time there is no prohibition against his holding a copyright. Still, in the main, the provisions of the old code are founded in justice, morality, and propriety. The same was true of the old Connecticut blue laws, but they became odious nevertheless. Specific penal legislation is needed for society at large, for no one has any voice in the constitution of society; it is an aggregate of "all sorts and conditions of men," into which we can not introduce a single person with a view to his fitness, and into which we can not prevent the entrance of a single individual on account of his unfitness. The medical profession, on the other hand, is a picked body, or should be; those who enter it come from the higher walks of life, they imbibe the traditions of a learned and honorable profession from their preceptors, and, when they start upon actual practice, they need no guide-boards to mark out the path of rectitude, for they soon find that they are following so delicate a calling that their only safety lies in the strict observance of their duties toward others.

Dr. Squibb argues that the various county societies that have instructed their delegates to vote in favor of the restoration of the old code pursued the proper course. That they had a perfect right to resort to this method of making themselves heard, we have no question. Theoretically, of course, the objection comes up that representation is only attendance by proxy, and that the representative's position should come as near as possible to what that of his constituents would be were they able to attend in a body—i. e., that he should not be absolutely fettered in regard to his vote, but that, sinking his own individuality, he should shape his course at the meeting in accordance with the impression that the actual proceedings would make on those who sent him, provided they were present. This ideal sort of representation, however, is seldom if ever attainable, human nature being what it is; so that, practically, we do not see what other procedure was open to these county societies than just the one which they adopted, wherefore we agree wholly with Dr. Squibb as regards their action. On the other hand, it seems to us fortunate that there is a goodly number of counties that have not instructed their delegates, for the discussion may take such a turn that some action now unlooked for will offer the best means of delivery from the serious disagreement that prevails at present.

DIRECTORIES FOR NURSES.

The difficulty of procuring skilled nurses, especially in cases of emergency, and in instances in which the services of a nurse are required for patients living in outlying localities, so that the time necessarily occupied in transportation must be added to that consumed in the hap-hazard search for a proper person, is one that almost any family is likely to find itself confronted with, and one in which, under ordinary circumstances, little assistance can be rendered by the physician, however much he may put himself to inconvenience to solve the quandary.

Boston ingenuity has set about remedying this unsatisfac-

tory state of things by the establishment of a nurses' directory, and such a decided success has been achieved that Philadelphia now has a like institution in successful operation, and we are informed that Washington, Cincinnati, San Francisco, and Toronto are taking steps in the same direction. We trust that New York will not long lag behind in a matter of such obvious utility.

Our space does not allow us to give the details in regard to the management and working of these directories, but it may be said, in general terms, that an office is established, and kept open day and night, under the direct supervision of a competent official, at which office a registry is kept of approved nurses. The office undertakes to keep itself informed as to the capabilities and personal qualities of the individual nurses so registered, and as to their whereabouts. By means of telegraphic or telephonic communication, together with special arrangements for a cab service, it is almost always possible to get any sort of nurse within a very short time, so that it often happens that an applicant is able to have a nurse under his roof in a suburban locality within an hour or two from the time he started on the quest—and, moreover, a nurse whom he has not taken blindly, but concerning whom he has definite and authentic information.

The expenses are met by a registration fee and by a fee charged to applicants. These fees are trifling in amount in comparison with the service rendered. It seems that the Philadelphia directory, an abstract of the first annual report of which has kindly been sent us, undertakes to supply wet-nurses. We regret to see that during the first year of its operation its expenses were largely in excess of its income, and we heartily trust that the favorable anticipation of the committee, Dr. W. W. Keen, Dr. Albert H. Smith, and Dr. S. Weir Mitchell, for its second year may prove well founded.

PYÆMIA OF LONG DURATION.

In the "Cincinnati Lancet and Clinic," for Nov. 25, 1882, R. J. Porre, D. D. S., reports the following extremely interesting case, which illustrates the close connection sometimes existing between dentistry and general surgery:

The patient was a man fifty-two years old, who in his youth had been somewhat noted as an athlete. For thirty years he had been a great sufferer, both mentally and physically, and was often confined to his room and bed for months at a time for treatment and recuperation. At no time during that period can he recollect that he was free from pain in some part of his body. He recalls that his troubles began with swelling and inflammation of the right side of his face and head, to the extent of closing his jaws and forcing him to liquid diet for a time. In a short time after the swelling had subsided tumors or boils appeared on different parts of the body, some of them secreting surprising quantities of pus. These have continued in an uninterrupted series—sometimes single, sometimes in groups, invariably containing abnormally large cores, which, after removal, left receptacles for the secretion of pus or a sanious fluid which continued to discharge for months before subsiding, and then only to give place to others of like character on other parts of the body. His hands and feet were constantly affected by an itching and burning eruption, or were a mass of boils and de-

generated and sloughing tissue. In this way he was rendered utterly helpless for many weeks at a time, and during some attacks alarming apprehension was felt that he would lose one or both hands or feet.

The throat and vocal organs were frequently so implicated that he lost the power of speech; respiration was at periods difficult and painful from spasmodic contraction of the diaphragm and muscles of the throat; the bowels for twenty or twenty-five years had been almost constantly so constipated and so affected with spasmodic constrictions (notably at the pylorus) that the daily use of artificial aids, such as bougies, enemata, and purgatives, was a necessity. During the same time, to urinate, the catheter was daily required, or the bougie to dilate most painful and obstinate spasmodic constrictions of the urethra. Phenomenally profuse, and consequently exhausting, night sweats resisted all the known methods of relief. Fevers varied in intensity and duration according to the severity of the complications, at times being intermittent for weeks. An important fact is that the pains always originated in and radiated from the right inferior maxilla, and, like electric shocks, involved not only that side of the face, head, and neck, but sent stiletto-like thrusts through the diaphragm, the bowels, bladder, limbs, hands, and feet. This fact alone should have led to an examination of the jaw, but it never did. The patient had been under vigorous mixed antisyphilitic treatment for thirty years, with only occasional interruptions to allow of a course of tonics, but no benefit had at any time been experienced. The case finally came under the charge of the narrator for examination as to the cause of the pain in the jaw. He found an abscess and caries of the jaw, at the angle and around the wisdom tooth. The tooth was extracted, the caries treated, and the patient was cured.

Proceedings of Societies.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

A STATED meeting was held December 7, 1882, Dr. T. M. DRYSDALE, Vice-President, in the chair. Dr. R. P. HARRIS being called temporarily to the chair,

Dr. T. M. DRYSDALE reported the following case of UTERINE MYO-FIBROMA.—An unmarried lady, thirty-one years old, of Trenton, N. J., consulted me January 18, 1879, as to the advisability of an operation for the removal of an abdominal tumor. On examination it proved to be a uterine fibroid, hard, smooth-walled, and moderately movable. It filled the lower part of the abdomen, and extended upward to about an inch above the umbilicus. A peculiar feature in the case was the presence in the lower part of the tumor of a large vessel with an aneurismal thrill, which could be felt through the upper part of the left side of the vagina. As her general health was good, the tumor producing no inconvenience except by its size, and the menses regular in every respect, I advised against an operation, and directed her to take chloride of ammonium in ten-grain doses three times a day, and at her menstrual period thirty-drop doses of the fluid extract of ergot at the same intervals.

She continued this treatment for two years, the tumor in the mean while slowly increasing in size. At the end of this time, finding no diminution in the size of the growth, and becoming discouraged, she abandoned all medicines. The tumor continued to grow steadily, and became much softer in its upper portion. An examination made December 9, 1881, showed the tumor growing in all directions. It now projected into the pelvis behind the uterus, filling this part with a hard, nodu-

lated mass, while above, as has been stated, it continued to soften as it ascended, giving it the feel of a cystic growth.

From this time it continued to grow rapidly, and by July, 1882, it was pressing against the liver and filling the whole abdomen, except the epigastric and left hypochondriac regions. Her general health was seriously impaired, and she had emaciated considerably. On examination, the uterus was found displaced toward the right side; the sound entered five and one quarter inches in the same direction. When in the uterus, the sound did not follow closely the motions given to the tumor, while the tumor itself was found to be more fixed. The menstrual vessel had enlarged considerably, and the thrill was much stronger.

Although I had dwelt upon and fully acquainted her with all the dangers of such an operation, yet she was very anxious to have the tumor removed, and as delay increased the danger, I proposed an exploratory operation, with the understanding that if the tumor could not be taken away with ordinary safety, it should be left undisturbed, but in that case, if possible, the uterine appendages should be removed, and the arteries in the broad ligaments tied.

The operation was performed November 2, 1882, in which I was assisted by Drs. W. P. Buck, W. S. Stewart, L. Harlow, of this city; Dr. I. Shellenberger, of Germantown; Dr. I. Eshelman, of San Francisco, and my son. An incision of about three inches in length was made through the abdominal wall, midway between the umbilicus and pubes, down to the peritoneum, which was cautiously opened, exposing a dark-red tumor with a rough surface. The structure of the tumor was soft, and it appeared highly vascular. Fearing to tear it, I passed my hand with extreme caution between it and the abdominal wall down toward the usual location of the ovaries, but could not reach them. Great difficulty was experienced in doing this, owing mainly to the rigidity of the abdominal walls, which kept them in close apposition to the tumor, and it required the exertion of considerable force to separate them. While thus attempting to reach the ovaries, I unfortunately tore a small opening in the upper surface of the tumor, from which the blood flowed freely. It was found that this bleeding could be controlled only by pressure, for the structure of the growth resembled a sponge, and was so soft and easily torn that a ligature was worse than useless, as it would cut through the loose tissue, leaving a larger bleeding surface. It being impossible, then, to arrest the bleeding by any other means than pressure, I was compelled to continue the operation for the removal of the tumor. To do this the incision was extended to three inches above the umbilicus, and downward nearly to the pubes. The tumor was attached above and behind to the mesentery, while beneath it was adherent to the broad ligaments and ovaries which lay under it, these bodies having been displaced to such an extent downward and backward as to be completely out of reach until the tumor was raised. The pelvic portion was strongly adherent to the surrounding parts. The mass was removed from the abdomen with considerable difficulty, but when this was accomplished it was seen to spring directly from the fundus of the uterus by a broad pedicle. A large clamp was applied to this and the tumor cut away. The adhesions were soft and brittle, and tore readily, leaving a rough, coarsely granular, or spongy surface, and from every adherent point poured out blood. The main bleeding was from the adhesions around the brim of the pelvis and to the broad ligaments. The tissues about these adhesions were ragged, and the vessels difficult to secure, but I succeeded in arresting the hæmorrhage. On raising the intestines, which had been thrust out by the contraction of the abdominal muscles, the torn mesenteric attachment was found to be bleeding freely. This surface required a great number of ligatures.

Immediately upon the withdrawal of the tumor from the abdomen the patient became pulseless, the skin pale and moist, and, in fact, all the signs of intense shock presented themselves. This was before any serious hæmorrhage had occurred. The active bleeding which immediately succeeded prevented any attempt at reaction, and although heat was applied, brandy given freely by the mouth as long as she could swallow, and hypodermic injections of brandy and morphia used, she sank, and died just one hour after the clamping of the tumor.

This case is of great practical interest in view of the strenuous advocacy by many recent writers of the operation for the removal of the uterine appendages as a comparatively safe method of arresting the growth of uterine fibroids. It proves that in these large fibromata such an operation is not only hazardous, but may be extremely difficult, and that, in fact, we can not even be certain that we can reach these appendages, for in this case so completely buried beneath the tumor were the ovaries and ligaments that neither could be found until it was raised from its bed, when they were discovered adhering to its lower portion. In an operation which I performed last winter the same difficulties were experienced; the ovaries could not be reached until the tumor, which was extremely large, weighing nearly a hundred pounds, was raised out of the abdomen. These, added to many other cases which I have met with, show that in large uterine tumors the removal of the uterine appendages may prove quite as dangerous as the extirpation of the growth itself, and be utterly impracticable unless the tumor is turned out from the abdomen. Now, if this should have to be done in order to reach these bodies, which would, of course, necessitate the detachment of adhesions and risk a shock by the disturbance caused by raising the mass, it would undoubtedly be better practice to leave the uterine appendages untouched and remove the tumor itself.

This case teaches another practical fact, which I have not found alluded to by writers on this subject: that when we meet with the soft variety of these growths, the certainty of hæmorrhage difficult to control is added to the other risks of the operation; and if the character of the tumor is recognized in time, and the presence of extensive adhesions determined, the safest plan for the operator to follow is to leave the tumor untouched and close the wound.

Dr. B. F. Barry, in response to a call from the chairman, discussed Dr. Drysdale's effects of ammonium chloride and ergot as administered by him in this class of cases. Did not ergot, when given during the menstrual flow, increase the quantity of the discharge? Did ammonium chloride have any effect in reducing the size of the tumor? He had used ammonium chloride a great deal; in fact, he gave it in every case of uterine fibroid that came under his care, but he had not seen or expected much from its employment; he considered it an alternative; it made the patient feel better, but he had not seen any reduction in the size of the tumor follow its use; it relieved the painful flushings connected with the existence of a uterine fibroid or the menopause. He was not very sanguine as to the effects of ergot used in any way, hypodermically or otherwise, in reducing the size of a uterine tumor, and it certainly could effect nothing in the case of a pediculated sub-peritoneal uterine fibroid.

As to the hazard of the operation, under the conditions existing in the case narrated by Dr. Drysdale, it could not be too strongly expressed; but there had been instances of recovery under conditions apparently as desperate as those just detailed. The patient referred to by Dr. Harris (Chairman *pro tempore*), was operated upon by Dr. Goodell. She was a married middle age, who had been suffering from profuse hæmorrhage which was endangering her life. This hæmorrhage was the result of the existence of a large uterine tumor, and Dr. Goodell

decided to attempt oöphorectomy as a means for her relief. An incision three or four inches in length was made in the middle line of the abdomen. The large size of the tumor made it very difficult to reach the ovaries; one was, however, reached and successfully ligated, and removed without causing hæmorrhage, although the pampiniform plexus was very much enlarged. It was necessary, in order to reach the other ovary, to enlarge the abdominal incision and roll the tumor over. It was found and removed, but a large plexus of veins was ruptured in the turning, and the hæmorrhage was frightful, the blood escaping from both ends of the vessels; ligatures were passed through the substance of the tumor, and finally succeeded in stopping the loss of blood. The doctor thought he might be compelled to remove the entire uterus to stop the hæmorrhage. This had happened to Knowsley Thornton.

This patient recovered, but Dr. Baer had seen death from peritonitis result in similar cases from the exploratory incision alone, the tumor and ovaries being found to be in so vascular a condition that Dr. Goodell was afraid to complete the operation.

Dr. HARRIS remarked that he was present at this operation, and was a close observer. The veins were ruptured during turning of the tumor; there was a peculiar anastomosis of the large venous trunks at the point of rupture. In this case the tumor had formed no adhesions.

Dr. Harris had been present at an operation by Dr. W. W. Keen in a similar case. The tumor was smaller, but the hæmorrhages had been so profuse before the operation as to leave the patient waxen in appearance. In this case the tubes were tied close to the uterus, and were removed with the ovaries.

Dr. BAER remarked that Dr. Goodell had been very successful in operating by removing the ovaries for the cure of metrorrhagia, the consequence of uterine fibroids.

Dr. GITHENS, in answer to the first query by Dr. Baer, remarked that, although not successful in relieving menorrhagia by the internal use of ergot, he had had very satisfactory results from the use of ergotin suppositories in cases in which there was no tumor present.

Dr. A. G. B. HINKLE alluded to several cases in which he had used ergot for the relief of menorrhagia due to the presence of uterine fibroids. He had given it three days before, during, and for three days after the close of the period; he also gave ammonium chloride in ten-grain doses, three times a day, all the time. This treatment had produced undoubted effects, and in some cases the tumors had disappeared.

Dr. HENRY BEATES had used ammonium chloride in the treatment of a lady who had a large uterine tumor. He continued it one year with marked effect. The menopause came on two years afterward, and the tumor had entirely disappeared.

Dr. Beates made some general remarks about the microscopical appearances in hard and soft uterine tumors, and thought that the effect of ergot would depend upon the presence or absence of muscular fibers as a component part of the tumor.

Dr. DRYSDALE, in closing the discussion, urged upon the members the desirability of limiting the operation of the removal of the uterine appendages for the cure of uterine fibroids to small tumors, or to those in the early stage, and which had not commenced to undergo the softening process. He had noticed, in cases under his care, a small spot of softening begin in a previously hard tumor and progress until the change was complete. The tumor presented this evening had undergone this change, and had undoubtedly assumed a malignant type. Before the operation it felt as if it contained a fluid. Since its removal it had shrunk to about one half its original size from drainage of blood. From the description given during the debate, the tumor in the case of Dr. Goodell's differed from the

one presented this evening in being much smaller, harder, and free from adhesions. The hæmorrhage in his case came from a single laceration in the tumor, and could be controlled. In this case not only did the torn substance of the tumor bleed, but every detached adhesion poured out blood in abundance.

In reply to Dr. Baer's questions, he would say that ammonium chloride, in some cases of hard uterine tumors, was remarkably efficacious in reducing the size of the growths; he had repeatedly seen them entirely removed by the remedy. He had never known ergot to increase the loss of blood during the menstrual period when used for the cure of intra-mural tumors; ergot had a decided effect upon the nutrition of these growths, but he would not expect it to act upon pedicellated growths unless inside the cavity of the uterus.

Dr. HENRY BEATES had been called in consultation to see a case of metrorrhagia. Ten years previously the patient had suffered from miscarriage at the fourth month. Subsequently each menstrual period became more and more profuse and prolonged until, at the time Dr. B. first saw her, the loss of blood was constant, and the patient was pallid and reduced almost to a skeleton, her weight being but ninety pounds. The curette had been previously applied to the endometrium, with the effect of increasing the discharge. Dr. Beates introduced a sound, which passed to the left to a depth of five and a quarter inches; he introduced a laminaria tent of the largest size, and next day, by digital examination, discovered a sessile tumor; further dilatation enabled him to remove the tumor by evulsion. It was necessary to divide it to extract it through the os uteri. It was composed of fibrous and muscular tissue, and contained numerous dilated blood-vessels, which had been the source of the hæmorrhage before operation. Three years afterward the patient's weight had increased to one hundred and fifty pounds.

Dr. B. F. BAER read the following report of A CASE OF LABOR WITH TWINS.—E. S., aged twenty-two, and single, entered Maternity Hospital on the morning of November 2d, complaining of pains resembling those of the first stage of labor, although her gestation was computed to have reached only the beginning of the ninth month. These pains, she stated, began on the previous evening. Later in the day I saw her. Inspection of the abdomen showed it to be greatly distended and irregular in shape. By palpation I could readily outline, as I thought, more than one fetus, and by auscultation I very distinctly heard the heart-sounds of two children—one high up and to the right, the other below the umbilicus and to the left. I diagnosed twin pregnancy. Vaginal touch revealed the os uteri to be dilated to about the size of a silver half-dollar, the lower segment of the uterus and cervix to be rather elongated than rounded, as in a presentation of the vertex. After a time spent in deliberation a presentation of the feet was diagnosed. The pains were not strong, and they had very little effect on the cervix. The patient was in a fair condition, though somewhat excited. Her lower extremities were œdematous, her face was a little puffy, and her urine contained a small quantity of albumin. The heart-sounds of the children were strong. I ordered fifteen grains of the hydrate of chloral and twenty grains of the bromide of potassium to be given at once. This dose was repeated once during the labor. Her bowels were moved by an enema.

Three hours afterward the os was of about double the size of that found at the first examination. The pains, still feebly acting on the presenting portion, had very little dilating power. As there was no special reason why the labor should be hurried, I waited two hours longer, at which time the feet were well down in the cavity of the pelvis, and projecting through the os, though the membranes were still unruptured. As the first stage of labor had now lasted twenty-four hours, and the patient was

becoming tired, I felt that something more ought to be done to expedite the delivery; I therefore ruptured the membranes. One hour more was consumed before the feet reached the vulva. I now brought down the feet by extending the legs, and in a very short time after, without the least traction, the body followed as far as the shoulders, where it was arrested by extension of the arms. The arms were brought down as speedily as possible by carrying them forward over the face. The child showed by its movements that it was still living, and the cord was feebly pulsating. The latter was relieved from pressure as much as possible. It was imperative that the head should be extracted speedily, or the child would die, but for some reason it would not descend. I at once recognized, as the cause of the delay, that the head was extended, with its long diameter in the conjugate of the superior strait, and that it was not yet fully freed from the grasp of the cervix. I tried to flex the head and place it so that one of its antero-posterior diameters should correspond to the transverse of the superior strait, but could not, because, as I now recognized, the presenting portion of the second child was in the way. I could not reach high enough to bring the proper force to insure flexion of the head. I now very easily and quickly adjusted Simpson's forceps, when, by giving a slight oblique turn and carrying the handle of the instrument forward, the head flexed, and delivery followed almost immediately. Certainly, I think, not more than ten minutes elapsed from the time the body was expelled as far as the shoulders until the head was extracted. The child was alive, but in an asthenic condition, and, although the usual efforts at resuscitation were applied, it died soon after.

Examination now revealed a presentation of the right shoulder of the second child, and that the presenting part was projecting through the superior strait. The membranes were unruptured. Version by the vertex was performed by the bimanual method, the uterus stimulated by friction and pressure on the fundus, and the membranes ruptured. But the uterine contractions were very feeble, and it was some minutes before the head was secured from returning to its former position in the left iliac fossa, by having passed through the superior strait.

The uterus was now left to rest, with the hope that it would spontaneously regain enough power to expel the remaining child; but after waiting nearly an hour, and finding that the head had advanced very little, a drachm of the fluid extract of ergot was administered *per os*. This gradually spurred the uterus, and within thirty minutes afterward the second child was born, or one hour and a half after the birth of the first. The uterus was so much exhausted that it was with difficulty made to contract by friction and pressure on the fundus, and it would relax again almost immediately afterward. There was no evidence of separation of either placenta, in part or entire, because there was no hæmorrhage. Therefore I concluded to let the organ rest for a time for the purpose of recuperation. I waited more than half an hour, of course not disregarding the liability to hæmorrhage, open or concealed, and looking out for it. By this time the uterus was contracted pretty firmly around the placenta, which were attached in the neighborhood of the right cornu. I now tried again, very thoroughly, to express them by the Credé method, but failed. Traction on the cords seeming to indicate that the placenta were adherent, the only thing left to be done was the introduction of the hand. This I did with considerable difficulty. The uterus was firmly contracted at all points, except in the right upper portion, where it seemed to be paralyzed or prevented from contracting by the presence of the placenta. This gave to the organ the so-called hour-glass shape. The placenta were both adherent. I separated and withdrew them slowly, and held the emptied portion firmly by the external hand until contraction was secured.

There was no further difficulty, and the patient left the hospital at the usual time.

I think the following points in the case of sufficient interest to warrant me in asking the society's opinion on them:

1. The conduct of the first stage of labor. Ought I to have hurried it more, and thereby prevented exhaustion of the uterus? I think not. As it was, the os was not sufficiently dilated to allow the head to pass readily.

2. The extraction of the after-coming head. Placing the antero-posterior diameter of the child's head in the transverse diameter of the superior strait, and facilitating its passage, if necessary, by external pressure on the fundus of the uterus—the method so graphically described, and so earnestly and properly insisted upon by Professor R. A. F. Penrose, as the proper plan of managing the head in ordinary breech presentations—was impracticable here, for the reason that the second child was in the way, both of placing the head transverse and of external pressure. Manual or forceps action on the head was the only resort. That I did not at once apply the forceps I am sorry, for delivery three minutes earlier might have saved the life of the child.

3. The choice of ergot in preference to the forceps as a means of facilitating the birth of the second child. The administration of ergot for the purpose of expediting the delivery of the child can not be too strongly condemned, as a broad rule, but that there may be an occasional exception I think must be admitted, and, also, that this is one. The os and other soft parts were dilated by the passage of the first child; the pelvis was sufficiently capacious, the presentation and position normal. There was, therefore, no obstruction to the rapid passage of the child were the power furnished by the action of the ergot. Moreover, that the uterus was worn out, and wanted time and stimulation to recover, was proved by the history of the labor, as related. There would have been great danger of hæmorrhage had the forceps been used to empty the uterus rapidly.

4. Morbid adhesions of the placenta, causing irregular contraction of the uterus, or contraction of the organ in every portion, except opposite the attachment of the placenta, where the contraction was not strong enough to separate them, giving the so-called hour-glass form to the uterus.

5. What influence had the ergot, if any, in inducing the irregular contraction? From my own experience, I would answer that I do not think it had any; first, because I almost always give ergot as soon as the child is expelled, and before the expulsion of the placenta; and, second, because I have never met with irregular contraction of the kind under discussion except in cases where the placenta was morbidly adherent.

The question, May ergot complicate the third stage of labor, by acting on the circular fibers of the uterus, at the internal os for instance, independently of the oblique and longitudinal fibers, incarcinating the placenta thereby? I should like to hear discussed. I take a negative view.

6. The presentations were unusual. The first child usually presents by the head, the second by the breech or feet. In this case the first presented by the feet, the second by the shoulder.

They were both males, and weighed conjointly twelve and a half pounds. The first child was the smaller of the two. This is unusual.

Dr. Harris had had under his care a woman in labor with twins. The first one expelled was a female weighing eight pounds; it presented by the breech. After it came away the os uteri and soft parts contracted, and an examination made by one who did not know of the birth of the first child would not have discovered evidence of the fact, and for the treatment of the cord. The bag of waters presented, and the os uteri was again dilated. Three and a half hours after the birth of the

first child the second, a male, was extracted by the assistance of the forceps; its weight was nine pounds.

Dr. HORACE WILLIAMS related his experience in a case of twins. The first child descended in the fourth position, and no rotation occurred, as it was held so by the second child; the pelvis was roomy, but laceration of the perinæum resulted.

Dr. B. F. BAEK also read the following:

A CASE OF UTERUS SUBSEPTUS, COMPLICATING THE THIRD STAGE OF LABOR.—Through the kindness of my friend, Dr. T. Stanton Crowley, I was permitted, on November 29, 1892, to see the interesting case which I here briefly describe.

After a rather tedious labor, in which the breech presented, Mrs. M. G., aged twenty-four, was delivered, two hours before I saw her, of her fifth child. The placenta was removed with some difficulty about half an hour after the expulsion of the child; but the membranes were retained by what was supposed to be an hour-glass contraction of the uterus, or contraction of the internal os.

I found the uterus well contracted, but somewhat irregular in shape, as felt through the hypogastrium. The internal os was contracted closely around a portion of the amniotic sac, which was projecting through it. I gradually passed one finger and then two through the os, and found that the membranes were pressed upon and retained by a firm substance, which obstructed the passage. After still further dilating, I tried to pass my hand, or as much of it as was necessary to reach the membranes, which I traced to the left cornu. In doing so my thumb was directed to the right, by the obstruction above mentioned, and passed into another cavity, independent, apparently, of the one in which my fingers were. The latter cavity was comparatively large, and contained the membranes. My first impression was that I was grasping a fibroid tumor which had been flattened by pressure, or possibly a supplementary placenta which was detached and lying edgewise, but the result of further investigation proved that it was neither. I next removed the membranes—nearly the whole of the fetal sac—and then made a more thorough examination. Again passing my hand partially into the uterus, while with the external hand I made counter-pressure on the fundus, my fingers entered a comparatively large cavity toward the left. This was rough—the placental site—and cylindrical in shape. My thumb, as before, passed to the right and into another cylindrical cavity, small, compared to the left, and smooth. Grasping the septum which separated my thumb and fingers, I found that there was a complete division of the uterine cavity into two unequal parts. The septum was wedge-shaped, with the blade of the wedge below, ending at the internal os, and, therefore, not dividing the cervical cavity. Externally the organ was not perfectly symmetrical and smooth, but at the point opposite the septum a slight depression was felt.

This is the *uterus subseptus unicollis* of Kussmaul, or a uterus which is divided in the cavity of the body only, the septum stopping short at the internal os, not dividing the cervical cavity, therefore. The slight sulcus on the external surface makes it approach the form described by the same author as the *uterus bicornis subseptus unicollis*.

I now became interested in the history of the former gestations and labors of our patient, and learned that this was her fourth labor and fifth child.

The first was a twin pregnancy, and terminated in premature labor in the seventh month. There was an interval of more than an hour between the birth of the first and second child, and another interval of fifteen minutes between the expulsion of the placentæ. And they did not have even a membranous connection. Did each cavity have its own independent ovum, therefore? Not necessarily, but it is highly probable, because, as a rule, the placentæ of twins have a membranous connection at

least, and in those uncommon cases where they are entirely separate, may not each fœtus have had its own independent chamber furnished by one of the forms of double uterus?

The second and third gestations went to term, but the labors were both complicated, requiring the aid of the forceps to supplement the imperfect expelling power of the uterus. We can readily understand why the uterine force was not applied to the best advantage on the fetal ellipse in a case of this kind.

The fourth and last labor was complicated in its third stage in a manner which is new to me.

May not some other of the complications of the third stage of labor be due to an undetected malformation of the uterus, resulting from arrested development? For instance, the perfect hour-glass shape which a few observers are sure they have met with. The *uterus bicornis subseptus*, a form of malformation where the horns diverge, and where a septum extends into the cavity, dividing it into two, furnishes a case in which the finger would encounter a point of constriction before it could enter the cavity containing the placenta; and externally the hand would detect the apparent constriction at the bifurcation of the cornua. But you will answer that bicornate uterus is very rare. So is perfect hour-glass contraction of the uterus; and the malformation of the uterus might not be so rare as supposed if it were detected in every instance where it exists.

"Busch mentions a case of uterus bicornis septus in which an exhausting hemorrhage occurred, in consequence of the attachment of the placenta to the septum, which not contracting, the vessels remained open." (Klob.)

This malformation may account for some of the cases of superfœtation, and menstruation during the early months of gestation. In this case the catamenia were absent during the whole of every gestation.

Dr. R. G. CURTIN had that morning delivered a woman of twins; after the uterus was emptied and well contracted, a strongly marked sulcus could be felt in the fundus.

Dr. DRYSDALE had under his care a woman whose uterus was divided by a complete septum.

Dr. W. S. STEWART inquired if any previous examination indicated a want of symmetry, or if it resembled an extra-uterine pregnancy.

Dr. BAER had not seen the patient until after the birth of the child, and did not ask about the point mentioned by Dr. Stewart. Dr. Goodell had reported a case of supposed extra-uterine gestation in which labor came on naturally. This type of uterus might seem to be very rare because it was so difficult to recognize. The presence of the septum would never have been suspected in this case had it not been found in the attempt to remove the imprisoned placenta.

Dr. HARRIS said that Dr. Goodell was uncertain of the character of the pregnancy, although every diagnostic test but one indicated that it was extra-uterine. This exceptional condition was the sensation of muscular contraction in the presumed cyst wall when the hand was applied to the abdomen. Not being able to reconcile this action with the development of a tubal pregnancy, he determined to trust the case to nature, and sent the woman to the Preston Retreat, where she was delivered naturally in a few days. The uterus was double, and was twisted on its axis, and the empty cornu was posterior, admitting the sound in the median line as into an empty organ.

QUARTERLY REPORT ON SURGERY.

No. XIII.

By CHARLES B. KELSEY, M.D.,

SURGEON TO ST. PAUL'S INFIRMARY FOR DISEASES OF THE RECTUM.

HERNIA OF A PART OF THE WALL OF THE BOWEL.—Dr. Albert ([*Gesellsch. d. Aerzte in Wien.*] "*Wien. med. Woch.*," Nov. 4, 1882) gives a short explanation of the condition known as hernia of a part of the wall of the intestine which was described by Ritter in 1849, and the possibility of which has been denied by Roser. The latter holds that the whole wall of the bowel may be found in the mouth of the hernial sac, even when only a part is found in the sac itself, and that it is, therefore, a mistake to speak of a hernia of one wall of the bowel alone. König admits the condition, but believes a previous diverticulum to be necessary. Professor Albert operated upon one case where every precaution was taken to discover the exact condition. The whole sac and the mouth of the sac were laid open, but only one wall of the bowel was found protruding, and in this way the intestinal caliber was decreased, but no diverticulum was present, as was proved by the fact that when the gut was pulled out all protrusion disappeared. Even had not the protrusion entirely disappeared, it is possible to suppose that a diverticulum may be formed by the incarceration when it had lasted several days.

An incarceration of the intestinal wall of this variety can only take place after sudden and violent effort; and this form of hernia may be divided into acute, chronic, and congenital. In the acute form the incarceration may take place so quickly as to lead to a diagnosis of acute poisoning. As a result of pressure by the abdominal muscles, an intestinal loop is pressed against the point of least resistance—the mouth of the sac—and the amount which protrudes depends upon the length of the mesentery, the amount of the pressure, etc.

The chronic variety is due to a complete adhesion of the

hernia to the wall of its sac. A lesion of this kind is produced gradually, and exhibits the clinical history of gradually increasing stenosis, which, by accidental causes, may lead to a complete closure of the bowel.

In the case of a congenital diverticulum the condition is quite different. In this variety the intestinal caliber is not at all decreased, even though incarceration exist, and there is no hindrance to the passage of feces.

THE CONTINUED SUTURE FOR WOUNDS.—Dr. LUDWIG ("Centraltbl. f. Chir.," Sept. 16, 1882) has much to say in favor of the continued suture in all kinds of wounds. He has used it in all sorts of cases, and believes that, with occasional slight modifications, it is capable of a much more varied application than it has ever received. It is simple in its performance, gives a very accurate adaptation of the edges of the wound, and, therefore, greatly facilitates primary union. He has used it in some remarkably large wounds, as, for example, one extending from the anterior superior spine to within a hand's breadth of the knee joint, with entire satisfaction. He has used it in amputations, resections, amputations of the breast, extirpation of tumors, and in the operation for phimosis. He recommends its employment also in cases of intestinal resection, laparotomy, and in wounds of veins.

Dr. Bakó (*Ibid.*, Nov. 4, 1882) takes up the article by Tillmanns and adds much to what he has said in favor of this form of suture. He describes minutely his way of using it, of fastening the ends, etc. He begins it with an ordinary knot-suture, and, after having gone the length of the wound, cuts the thread, leaving an end about three centimetres long, in which he ties a simple knot to prevent its being withdrawn. This is a sufficient fastening when no great amount of tension is to be expected.

THE REDUCTION OF OLD SUBCORACOID DISLOCATIONS.—Dr. E. Ceppi ("Rev. de chir.," Oct., 1882) has advocated before, and now writes again in favor of Kocher's method of reduction in subcoracoid dislocations. At first the method was supposed to be applicable particularly to recent dislocations, but more numerous trials have demonstrated also its great utility in old cases. The method, briefly stated, consists in the following movements, which are practiced without anesthesia, the patient sitting in a chair and the physician kneeling with one knee on the floor by the affected side. An assistant may stand behind the patient and manipulate the scapula, but this is not considered necessary: 1. The forearm is flexed at a right angle with the arm, and, by the aid of the surgeon's right hand and thumb, the elbow is firmly fastened against the trunk. 2. While holding the elbow exactly in this position, the surgeon carries the left hand of the patient outward (the dislocation in this case being on the left side) slowly, gradually, and without shock. By this means the humerus is made to rotate in the same way. The movement is stopped at the moment a notable resistance is felt. 3. The elbow is carried upward and a little inward, while the forearm remains constantly flexed at a right angle and the hand is strongly forced outward. The arm thus reaches a plane almost perpendicular to the anterior plane of the body. During this manoeuvre the surgeon rises little by little from his knee. 4. It remains only to affect the rotation of the arm inward and to carry the hand of the patient to the healthy shoulder.

Kocher has been successful with this method in twelve out of thirteen old cases, the time of the existence of the condition being three weeks in one case, five weeks in two cases, seven weeks in three cases, three months in four cases, and four months in two cases. A list of twenty cases is appended to the article.

NEW METHOD OF REDUCTION IN DISLOCATIONS OF THE HUMERUS.—Dr. J. E. Kelly ("Dublin Jour. of Med. Sci.," Sept.,

1882) has described a very successful and simple method of reduction in dislocations of the humerus. For the operation, the selection of a couch or bed is of importance. It should be firmly fixed, and hard, and, when a choice is practicable, the author prefers for the subglenoid dislocation that it should be about three inches lower than the great trochanter of the operator. For the anterior dislocations, one a few inches lower than this is preferable, and, for the posterior, it should be a little higher for the force to be applied advantageously in the direction of the glenoid cavity. The patient should be placed as close as possible to the edge of the couch, on his back, with his head low. In order to make the description intelligible, the author divides his operation into two stages. The first, or preparatory stage, is the one in which the surgeon assumes the most favorable position for the operation. He places the injured arm at right angles with the body, and, standing against it, with his side to the patient, and his hip pressed firmly, but not roughly, into the axilla, he folds the arm and hand of the patient closely round his pelvis, and fixes the hand firmly by pressing it against the crest of his ilium. The second stage, during which the reduction is accomplished, is very simple, consisting merely in a rotation of the surgeon's body away from that of the patient with a force and rapidity which necessarily vary with the peculiarity of the dislocation—some yielding most readily to a sudden and powerful effort, and others to gentle and gradually increasing traction.

In reviewing this manœuvre, the author briefly contrasts the substitutes which it affords with the recognized methods of making extension, counter-extension, and coaptation. In the extension, instead of the grasp of the operator, which is often inefficient, the clove-hitch, or other knot, the special bracelets, combined with flexion of the forearm, bandages, chamois, or adhesive plaster, he proposes the simple folding of the arm, forearm, and hand of the patient around the pelvis of the operator, which, forming a series of angles, distribute the resistance so as to enable the operator, with one hand, to afford sufficient fixity for the application of the powerful extending force. For the limited strength of the operator, the uncertain and mutually obstructive force derived from numerous assistants, or the dangerous and sometimes disastrous mechanical extension by pulleys or adjusters, he substitutes a perfectly controllable and easily sustained power of some hundreds of pounds, derived from nearly all the muscles of the trunk and of the upper and lower extremities.

Again, for counter-extension—which must have been a matter of great difficulty when such measures as the split sheet, the fixation-table, the albi, or the special belts, the numerous assistants, the suspension of the patient over a door, through a ladder, or from the ceiling—the author suggests merely the weight of the patient's body, and the resistance afforded by its traction or friction over the rough surface of the couch.

For coaptation, in lieu of the various fulcra, such as the heel, knee, bed-post, special balls, jack-towels, etc., he supplies one which is equally safe and efficient, inasmuch as the well-padded gluteal region is unlikely to produce a rupture of the axillary artery, or similar accident, and because, in the torsion of the body, the hip materially assists by forcing the head of the humerus toward the glenoid cavity, and by its volume it makes the extension tend to the desirable angle of 45° , which places the deltoid and supra-spinous muscles in the most favorable condition. For any additional manipulation the surgeon has the hand next the patient's axilla disengaged for such manœuvres as lifting the head of the humerus into the cavity, making traction upon it forward, or pressure backward, according to the nature of the dislocation. The fixation of the scapula is a point of considerable importance, and is secured by its position between the

couch and the body of the patient, while its inferior angle is supported by the gluteal region of the operator.

One of the great advantages of this operation is the ease with which the surgeon can reduce a dislocation without anesthesia, without assistance, and without the appearance of any violent exertion. Should greater extension be necessary, it may easily be applied to the affected arm by another assistant, and counter-extension may be increased as easily by pressure on the sound shoulder or the pelvis.

TWO NEW METHODS OF REDUCING DISLOCATIONS OF THE FEMUR.—The same author (*Ibid.*, Oct., 1882) also describes very clearly two new methods of reduction in dislocations of the femur which are easily applied and extremely efficacious. For the purposes of his description, he divides all dislocations of the femur into anterior and posterior. The following case illustrates the method in the latter form: The patient was a man of such remarkable muscular development as to have gained for himself the title of "King of the Quay Porters," a body distinguished for their strength and endurance. The author's colleague on three occasions consulted with the hospital staff and with other eminent surgeons. Guided by his personal knowledge and the suggestions of his friends, he caused special apparatus to be constructed, from which he expected increased facilities, and ineffectually tried every recognized method of reduction. At the last consultation the author obtained permission to test an expedient which had occurred to him. He fixed the patient's pelvis firmly on the floor, and, standing over the limb, he flexed it, and placed the patient's foot between his own thighs; then, passing his forearms under the patient's knee, he made vigorous traction upward, and, to the relief of all, effected the reduction.

By this favorable result, and a successful experience of more than six other cases, in some of which many methods were tried, he has been able to develop the details of the procedure, which are thus described: Three strong screw-hooks are inserted into the floor, close to the perineum and each ilium of the patient, and to these hooks he is secured by a strong bandage or rope. The injured thigh is flexed at right angles to the patient's body, the foot and lower extremity of the tibia are placed against the perineum of the surgeon, who, bending forward, with his knees slightly flexed, passes his forearms behind the patient's knee and grasps his own elbows. He is now in the best position to accomplish the reduction, and with this object he exerts his strength to draw the femur upward, the action being generally efficient; but, when necessary, circumduction may be combined with extension, as the surgeon, while maintaining traction, sways his body toward the patient's uninjured side, then toward his head, then outward, and, stepping backward, he lays with a sweep the injured limb by its fellow, and thus the dislocation is reduced. In ischiatic dislocations a bandage, upon which an assistant may make traction, can be passed around the thigh close to the trochanter, and may be useful for the purpose of liberating the head of the bone from the sacro-sciatic foramen.

By this method the extension is applied in the most approved direction, and with the greatest economy of force, as the muscles of prehension are hardly called into play, being only required for the slight effort necessary to fix the hands on the elbows, while the forearms are flexed by their numerous and powerful muscles, and the patient's leg is kept in position by being a lever of the third order; and its displacement, owing to the unfavorable point to which the power is applied, would require a force of over a thousand pounds. The agency for accomplishing extension which the author substitutes for the pulley is ample, under perfect control, and sustainable, if necessary, for a considerable time, being derived from the most powerful muscles of the body—those of the back, shoulders, and

lower extremities. It is an adaptation of the feat termed by athletes "raising" or "lifting a weight," which affords an example of the most powerful of human dynamics—reaching, in some instances, to eight hundred or one thousand pounds, the average being from three hundred to five hundred pounds. The counter-extension is simply limited by the strength of the bandage, the hooks, and the floor; and the boards are secured from misplacement by the fact that, in addition to his own weight, the operator transmits to them a resistance equal to the power he exerts. The screw-hooks should have a deep thread, and should be inserted at an angle obtuse to the body of the patient, in order to afford the greatest resistance.

For anterior dislocations the author proposes the following method: The patient is placed on his back on a bed or table of such an elevation that his pelvis is nearly as high as the trochanter of the surgeon. A bandage passed round the pelvis, and secured on the side of the table or bed farthest from the dislocation, affords efficient counter-extension. The surgeon, with his face directed toward the dislocated joint, stands on the inner side of the injured limb, with his trochanter pressed firmly against the femur; bending the leg behind his back, he grasps the ankle with the corresponding hand, and is in the position to effect the reduction. He now rotates or turns his body away from the patient, thus making traction on the femur in the most favorable direction, and at the same time pressing its head toward the acetabulum. The operator has one hand disengaged for the application of minor manipulation should it be necessary.

The author takes pains distinctly to disclaim any intention of proposing a substitute for the great triumph of modern surgery, the treatment of femoral dislocation by simple manipulation during anesthesia. But, in case of the failure of this method, that of the author offers many advantages. It also promises to render the surgeon independent of anesthesia, assistants, and mechanical power, as in several of his cases he has reduced dislocations without aid from any source.

THE CHOICE OF MATERIAL FOR THE LIGATURE OF ARTERIES IN THEIR CONTINUITY.—Dr. B. May ("Brit. Med. Jour.," Oct. 14, 1882) discusses the relative value of several of the materials used for ligatures. The choice is narrowed, at the present time, to some form of animal tissue—as silk, catgut, or the strip of ox aorta recently advocated by Mr. Barwell. Whichever is used, it is cut short, and the wound closed over the foreign body, in the hope of obtaining primary union. The best material is that by which this requirement is most surely fulfilled, and which, at the same time, effects a permanent barrier to the circulation. Silk, even the best, and with the most careful antiseptic precautions, can not be relied on for the former purpose. Though the peritonæum has the power of encapsulating it, the connective tissue only does so as a lucky accident, and, more often than not, strangulation of the outer coat of the vessel proceeds to ulceration, by which the ligature is cast loose. By means of catgut a true subcutaneous ligature can be insured, but the permanent occlusion of the vessel is not so certain.

In the well-known case of Spence, in 1869, the catgut softened and relaxed its hold upon the common carotid with a fatal result. This case and others occurring at the same time were not treated with antiseptic precautions. Since then Lister's incessant labors have culminated in the chromicized catgut, which "will retain its hold on a vessel for three weeks, and yet become absorbed or encapsulated." This appears to be the perfection of a ligature.

The author has, during the past year, ligatured four large arterial trunks in their continuity. In three cases he used ordinary catgut; in the fourth, chromicized gut. In the last case the result was not so satisfactory as in the other three, for the

wound did not heal throughout its entire extent, and a small sinus remained for a long time, which seemed to lead down to the ligature. Inasmuch as the writer could discover no failure in the antiseptic precautions in this case, he believes the failure to obtain primary union throughout the whole wound may fairly be attributed to the ligature employed.

THE LARYNX-FORK FOR REMOVING LARYNGEAL NEOPLASMS.

—Voltolini, of Breslau ("Arch. of Laryngol.," Oct., 1882), describes and figures this instrument for the first time in an American journal. He does so, as he says, on the one hand, to quiet those of his colleagues who imagine that he operates only with the galvano-cautery apparatus, and recently with the sponge; and, on the other, because he considers the instrument a very efficient one. The larynx-fork is an instrument sharp only within, combining guillotine, knife, forceps, and cutting-loop in one instrument, shaped, as its name indicates, like a fork, the inner edges of the prongs being cutting surfaces, while the outer are smooth and rounded. It can, therefore, boldly be put into the larynx or pharynx without the fear of producing injury during the introduction or withdrawal, whether the patient heaves, swallows, or moves. A lancet-shaped knife acts as a sharp wedge; the point first pierces the tissues, and the two sharp edges enlarge the wound. The fork acts similarly, only in reversed order. It separates the soft parts to the same extent as a lancet-shaped knife of the same breadth, the only difference between the two instruments being that in the knife the point is downward, while in the fork the point of the two cutting halves is upward. The two inner free borders represent cutting knives, which end above in a circular cutting edge. The object of the circular space is that the soft tissues (pendant or cauliflower papilloma, etc.), after the knives have pierced them, may remain fixed in the hole, and eventually be torn away. The instrument is very slender and thin, like a larynx-probe, and can in a moment be bent at will, for only the points and knife are made of hardened steel, the rest of flexible material.

As a matter of course, the author has two forks, one in which the two prongs are behind each other, and one in which they are side by side. He uses them according to the seat of the neoplasm in the larynx—the first when it is attached laterally, the second when seated either at the back or front.

The author gives one case in which the fork was of signal service. The patient was nearly suffocating on account of a polyp, as large as a German plum, nearly completely filling the whole larynx, which, however, in spite of its enormous size, the mirror had not revealed to another physician, because the epiglottis nearly touched the posterior wall of the pharynx. On this account, every intra-oral operative procedure was excessively difficult. In such a case of urgent dyspnea even tracheotomy is dangerous, because the blood running down the trachea may occlude the small air-passage which is left. The author therefore tried intra-laryngeal operation. With great caution he used the galvano-cautery, the only instrument which seemed permissible. In spite of the greatest caution, the irritation of the operation caused so much dyspnea that the patient had to remain sitting upright in a chair during a night and a day. But the consequent suppuration diminished the polyp to such an extent that the danger of asphyxia passed away, and holder procedures became possible. The operation also gradually became raised, and allowed a better view of the larynx. The large polyp was seen to consist of two portions: one above the vocal bands, almost completely filling the laryngeal space; the other, at least as large as a bean, below the vocal bands, projecting into the trachea. Galvano-cautery achieved most brilliant triumphs. More and more of the two projecting portions was destroyed, and the succeeding suppuration further reduced the

polyp. At length the lower tumor had become so small that it moved up and down during respiration, and caused, as it passed the vocal bands, a flapping noise which bystanders could hear. As the author considered it important not to let this lower portion of the polyp, perchance in the night, fall into the trachea, as it might have done under the continued use of the galvanocautery, he had a strong desire to remove from the larynx the whole tumor at once. The pendent position of the epiglottis and the inaccessibility of the larynx made it impossible to grasp it with the forceps. Then the fork came into play—one with the prongs behind each other. This delicate instrument was introduced between and below the vocal cords, the flapping piece was transfixed, and the fork and tumor withdrawn together. It required some force to free with the fingers the morbid mass from the instrument, into the opening of which it was tightly wedged. It measured one centimetre and a half in length, and three quarters of a centimetre in breadth.

DIFFUSE ANEURISM OF THE FEMORAL; OPERATION OF ANTILLYUS WITH ESMARCH'S BANDAGE; CURE.—Dr. D. Mollière ("Lyon méd.," Oct. 1, 1882) asks whether in all aneurisms of the extremities we should have recourse to indirect compression, either digital or mechanical; and, in case of the failure of this means, whether Esmarch's bandage should be applied. This, he thinks, is the only question which seems to occupy the minds of the surgeons of to-day; and almost all of the observations which have been published during the last few years have been directed toward the solution of this problem. The case of which he gives the details is intended to show that the old operation of Antyllus is sometimes indicated; and that the surgeon may find himself in the midst of threatening accidents, which can only be met by a free opening in the sac and the ligature of both ends of the wounded artery. He holds that by the use of Esmarch's bandage and antiseptic precautions the great dangers of this method may be avoided. These dangers are failure to find the wounded point in the artery in the midst of tissues infiltrated with blood, and constantly threatened with a terrible hæmorrhage; and, again, the risk of septicæmia and secondary hæmorrhage which arises from so large a wound exposed to the air, and to the fermentation of blood-clots. The method of Antyllus may at present be considered as harmless and easy. The ancient descriptions have greatly exaggerated the difficulties of the operative procedure, which is essentially simple when the circulation has been stopped by Esmarch's bandage.

The patient upon whom Mollière operated was a man, aged thirty-five years, in good general condition, who a few weeks before had thrust a pair of scissors into his thigh at the level of Hunter's canal. At the moment of the accident he had lost an enormous quantity of blood. On admission there was a cicatrix about one centimetre long, and covered with a thin crust at the point of injury. The thigh at this point was the seat of a very large, soft, diffuse tumor, having the volume of the fist, and located deeply among the muscular layers of the thigh. It was distinctly felt by the side of the popliteal space between the biceps and the muscular body of the internal region. It pulsated synchronously with the pulse, and, by placing an index of paper on the skin of the region, the expansive movements could easily be demonstrated. All these signs vanished when the femoral was compressed in the groin. On auscultation, a *bruit de souffle* was exceedingly well marked at the point of the cicatrix. The diagnosis was traumatic, diffuse femoral aneurism. The patient himself gave an exceedingly good corroboration of the fact that the aneurism was diffuse, for he had noticed that since his entrance to the hospital it had daily increased in size. It was noted as a singular fact that the region was normal in color, the skin had the same tint as the rest of the limb, and there was no trace of ecchymosis.

In the presence of so grave a lesion, what treatment was to be adopted? The author thought at first of indirect compression as the most simple and least offensive measure. By applying the compressor of Jacques Bonnet (a bit of wood and an elastic band) a rapid amelioration was gained, and at the end of two days the tumor had become immovable and silent.

A single consideration made the author hesitate at first in applying this treatment. Was the cicatrix of the wound solid enough to give security against a severe hæmorrhage? It inspired the author with little confidence; but the patient was exceedingly intelligent, and it was easy to make him understand what accident might happen, and what he was to do under the circumstances.

After he had been eight days in hospital he remarked to the surgeon that his leg was swollen, and that the skin of the thigh was edematous. At the same time he complained of suffering greatly. The temperature of the part was raised, and he had a light febrile movement. Two hours later he removed the compressor for an instant to change his position in bed, and instantly there was a gush of blood from the old cicatrix reaching a yard. To place his finger on the wound, and replace the compressor on the femoral, was the work of an instant for the patient.

Mollière, being called instantly, placed the patient under ether, while an assistant compressed the femoral with his fingers, and resolved to ligature the two ends of the artery in the wound and to drain the sac after having turned out the clots. This was done immediately, after having applied Esmarch's bandage, which was loosely placed over the affected point, lest too great compression should favor the infiltration of clots into the cellular tissue. An incision of six or eight centimetres was made over the course of the artery. This was found to be perforated on its internal aspect, showing an oval orifice about one centimetre long. Two ligatures were placed, one above and one below, and the artery was divided between them. An enormous mass of clots was then turned out, which were liquified, and showed no trace of organization. The muscles had been dissected by the blood, and the femur was denuded on its posterior surface and roughened—a condition so frequently seen in vertebræ in contact with aneurisms, but very rarely in the bones of the extremities. A counter-opening was made on the outer surface, and a drain passed through the wound, which was closed with five metallic sutures. Thanks to the bandage, the operation was absolutely bloodless, and was done with the greatest facility. All the antiseptic methods were followed as strictly as possible. The leg was enveloped in salicylated cotton; but over the wound only a light dressing was applied, and the Mackintosh was omitted, so that no secondary hæmorrhage might be concealed. No accident interfered with the progress of the cure. There was a slight edema of the back of the foot, which disappeared rapidly. During the first week the limb was immobilized in a large gutter of Bonnet, to prevent all movement. When the patient left the hospital, perfectly cured, he walked freely, and showed only two perfectly healthy cicatrices—one on the inside, and the other on the outside of the thigh.

A PLEA FOR THE NEW STATE CODE.—[We are indebted to the courtesy of the "Medical Record" for proof-sheets of the following document, entitled "The New York Code of Medical Ethics and Freedom in Consultation: a Presentation of the Case for the Non-Restrictive Clause in the New Code. By One of its Advocates." It concludes as too late for comment.]

Rules governing Consultations.—Members of the Medical Society of the State of New York, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine. Emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity" (Code of Ethics of New York State Medical Society).

The section in question simply *permits* consultation with legally qualified practitioners, whatever their therapeutic methods.

"But no one can be considered as a regular practitioner or a fit associate in consultation whose practice is based on an exclusive dogma, to the rejection of the accumulated experience of the profession and of the aids actually furnished by physiology, pathology, and organic chemistry" (Code of Ethics of the American Association).

The restrictive section in the old code forbade consultation with any but regular physicians, defining "regular" as above.

The question at issue is not primarily the utility, or otherwise, of consulting with any but those who call themselves "regular," but concerning the advisability and justice of the individual being allowed to do so if the welfare of the patient or of the community seems to demand it; but concerning the advisability and justice of allowing every physician to decide for himself whether he will or will not do so.

Reasons for the Change. Objection to the Old Restriction.—1. *It was inoperative.* For many years the number of cases of discipline for violation of this restriction has been extremely few. Although we have positive knowledge that consultations with so-called "irregular practitioners" quite often occur, we have been able to find no instance, occurring within recent years, when such cases have been subjected in New York State to investigation and discipline.

2. *It failed to insure prosperity.* We can find no evidence that the old restriction, while placing a formal barrier about regular medicine, has lessened the number of quacks, or injured their prosperity.

3. *It was opposed to the general interest of the public,* who never have understood, and never can be made to understand, the technicality on which the old restriction was based. It therefore injured the standing of the profession before the world.

The people and lay press throughout the country unanimously approve the action of the State Society in removing the restriction. Such a complete unanimity of opinion among all classes upon a question of morals should not be disregarded.

4. *It added to the suffering of all classes of human beings who were irregular.* It was a form of persecution which was just weak enough to act as a stimulus and help to the persecuted.

5. *It infringed on individual rights.* Our chartered medical societies have a right to say what shall be the moral qualifications of their members, judging them by the ordinary moral standards; but they have no right (morally) to impose a special line of conduct upon individuals, and say arbitrarily that such rule of action alone is right. This establishes a technical morality which is not only unjust, but is unphilosophical and at variance with the principles of modern ethics. Good and bad are only relative terms. A person, even if convicted of a crime by a lawful process, can be good in every sense, but is not. The motive is the main issue. A consultation with a "regular" phy-

sician may be dishonest and mercenary. Medical societies and codes may urge honesty of action and right conduct generally, but to prescribe specific things, and say that they alone are always right, is unwise and unjust.

6. *The definition of an irregular physician given by the old code does not describe all in this State who are classed as irregular.* If literally interpreted it would really permit consultation with many of this class. Whatever may have been the condition of medical education and morals at the time when the "American Code" was adopted, the number of those styled "regular" does not now embrace all who are educated, honest, and trustworthy practitioners. This is demonstrable in the experience of nearly every physician who has been for even a few years in practice in this State. The attitude of the defendants of the old code is therefore inconsistent.

7. *A legal wrong was done by the old code, in the opinion of eminent lawyers.* The State Medical Society is a chartered institution with certain powers by which it profits. Yet it used these powers to exclude from professional recognition and to injure persons whose legal status was exactly like that of its own members.

8. *It was a hindrance to securing medical legislation for the general elevation of the profession.* This has been illustrated in Massachusetts and other States, as well as in New York.

Advantages of the New Section.—Its advantages are summed up in this: that it does away with the objections just enumerated, to the old, restrictive code.

It is in harmony with general ethical principles which urge the discharge of our duty toward ourselves and our brother rather than the assumption of a special attitude toward a class prejudged and condemned.

It places the profession beside that of France and Germany, where the policy of ignoring rather than of actively opposing homœopathy and other dogmas is successfully pursued.

It gives opportunities for showing that the surest way to vindicate the superiority of scientific medicine is to let it come in contact and comparison with charlatanism.

Special Charges and Objections made to the New Section.—1. *That it was the work of specialists who wished to increase their consultation practice.* This charge has been laboriously, persistently, and insultingly made. While it has nothing to do with the absolute merits of the question, it is, we believe, entirely false.

The code was drawn up by a committee of five, three of whom were general practitioners; and three, also, were ex-presidents of the society, widely known and entirely trusted.

2. *That the code was rushed through the society hastily, by a small vote.* The new code was fully discussed, at great length, in two sessions, and was adopted by a vote of fifty-two to eighteen. Some who voted against it voted for the Roosa resolution, so that the majority for a merely non-restrictive clause would really have been larger. The meeting itself was one of the largest that the society ever held.

3. *That the new section is an entire surrender to dogmatic medicine, i. e., an acknowledgment of the truth of homœopathy, Thomsonianism, etc., and that it implies the confession of having previously held a false position.* The new clause simply means that we believe it unwise and unjust to forbid consultations with legally qualified practitioners. It advises nothing and admits nothing beyond the principle that there may be occasions when the rights of humanity should be considered paramount to the demands of trade-unionism.

The questions of "surrendering" or "admitting," however, we repeat, have no bearing upon the absolute right or wrong of the thing done. If the previous position was really wrong, it should be only fair to admit it. It should be remembered, moreover, that society progresses and requires new adjustments.

4. *That the homœopathist or other medical dogmatist can have nothing in common with the scientific practitioner, and that consultation between the two must, a priori, be absurd, futile, or even injurious.*—The code admits, does not advise, such consultations. It urges honesty, and if a doctor be honest and believe the above [sic], he need not consult with dogmatic or dishonest physicians. But even admitting the above [sic] proposition so far as relates to therapeutics, it does not

necessarily cover matters of diagnosis or general management. Furthermore, in this State, many so-called irregulars are not followers of dogmatic medicine.

5. *That it will lower the tone of the profession.* It is claimed that the removal of the restriction will lower the tone of the profession and lead to moral decline and decay.

It is impossible to prove such a charge, and only declamatory statements have so far been brought forward in evidence. Experience so far shows that individual morals are not appreciably affected by society codes. Doctors become good or bad as other persons do. The superiority of scientific medicine must be proved by its works. Societies can elevate medicine most by scientific work and criticism—which is their legitimate function. As regards ethics, they can only urge general right conduct. The present code continues to urge and demand this of its members; if they obey it they can not be made worse by having the privilege of consulting as conscience dictates. On the other hand, submission to a code of ethics which is believed to be unjust, oppressive, and opposed to the demands of conscience and the sense of humanity, is certainly not calculated to elevate the moral tone or inculcate honesty of principles.

THE COMMITMENT OF LUNATICS.—On January 4, 1882, the Senate of this State passed a resolution requesting the Attorney-General, Leslie W. Russell, and the State Commissioner in Lunacy, Dr. John Ordronaux, to report to the Legislature such amendments to the laws relating to the insane as might seem to them desirable. In pursuance of such request, they in turn asked the Medico-Legal Society of this city to state such changes as were deemed necessary. Quite recently the Permanent Commission of the society, to whom the matter was referred—consisting of Clark Bell, Esq., Austin Abbott, Esq., George H. Yaman, Esq., Jacob F. Miller, Esq., Dr. R. J. O'Sullivan, and Dr. Wooster Beach—have made a very careful report, which will demand the attention of the general public as well as members of both the medical and legal professions.

The Committee, in contrast with Mr. Russell and Dr. Ordronaux, take the ground that the whole system of lunacy laws is inadequate to the needs of the case, and should not be changed by amendments here and there, but should be examined carefully by a commission appointed for the purpose, and revised from beginning to end.

The main points considered were the proper safeguards to be thrown about the legal commitment to asylums, and the means to be suggested for discharge in case of erroneous confinement or the recovery of the patient.

The laws of the State at present allow a commitment to an asylum upon the certificate of two physicians of three years' standing; but the confinement shall not be longer than five days, unless within that time the certificate shall be approved by a judge or justice of a court of record in the county or district in which the alleged lunatic resides. The qualifications of the physicians, in addition to three years' practice, are that they shall be of reputable character, graduates of some incorporated medical college, and permanent residents of the State, which qualifications must be certified to by the judge. The Committee were of the unanimous opinion that it ought not to be in the power of any two physicians to commit to an asylum upon a simple certificate, and that no person, sane or insane, should be shut up for five days, or any other time, without due process of law, or the decree of a court of competent jurisdiction, and a full opportunity being granted for a hearing. The Committee are also of the opinion that the statutory qualifications of the examining physicians are radically defective. They say that the "physician may be perfectly respectable, of the highest character, and three (or even twenty) years' practice, and still, from lack of experience on this subject, not be entitled to act, especially in difficult, obscure, or doubtful cases."

In place of this provision the Committee advise that examiners in lunacy should be selected by a competent commission or tribunal, and should be only men who are peculiarly qualified by experience, skill, study, and attainments, to speak intelligently upon such cases. They also suggest that no judge should sign an order for commitment except after full and satisfactory evidence, by well-qualified medical experts, that the person was insane at the time; and that, if pos-

sible, such person should be brought into Court before the order is signed.

In answer to the objection that great harm might be caused by the violent acts of some madman before this machinery could be brought into operation, they say that such person or persons might be arrested for disorderly conduct.

In regard to the control of the insane after they are placed in an asylum, the Committee make several suggestions. First, that every person incarcerated should have at all times the right to communicate, by letter or mail, with counsel and friends; secondly, that every alleged lunatic should have the right at any time to have his mental condition examined by experts not connected with the institution in which he is confined, and that bulletins containing such information should be posted in places accessible to the patients; and, thirdly, that there should be an examination of every patient in an asylum at least as often as every six months, by experts specially appointed for the purpose, and unconnected with the institution in which the patient is confined.

As to the discharge of patients in case of erroneous confinement or recovery, the Committee do not advise any special mode of procedure, but suggest that the power now given by the laws to the physician in charge of institutions in the counties of New York and Kings, to absolutely discharge any patient upon signing a certificate that such discharge is safe and proper, is of very questionable propriety, and, if wise, ought not to be confined to these counties alone.

The powers now possessed by the State Board of Charities for the visitation and investigation of lunatic asylums the Committee regard as wise and beneficial.

The control of insane persons, exercised by any committee to whom they are given in charge by the courts, should always be open to supervision by the courts; and especially should this be the case in regard to removal beyond the State.

The question of the control of criminals acquitted on the ground of insanity, whether there can be any fixed time settled upon for their detention, and whether there should be any time before which application for discharge on the ground of alleged recovery could not be entertained, the Committee regard as of great importance, and suggest that the restoration to reason, as pronounced by experts, should be the test of detention or discharge, and that the element of time should not weigh. As a final suggestion, the Committee advise that there be no change in our divorce laws in order to allow incurable insanity as a ground for divorce.

The report of the Committee, as a whole, is an important one, and its suggestions are well worthy of the attention which the Legislature will no doubt give them.

A BAR TO AN ACTION FOR MALPRACTICE.—An interesting decision to physicians and surgeons was recently rendered in the courts of one of the Western States.

The services of a surgeon in a particular case were not regarded as satisfactory by the patient, and his bill was refused payment, and, in a suit brought to recover the amount of the bill, the patient defended on the ground that the services were of no value. The decision of the Court was in favor of the surgeon, and thereupon the patient brought a direct suit against him, claiming damages for malpractice. Upon the trial this suit was dismissed, the Court holding that the question of malpractice had been in effect adjudicated in the former suit under the issue that the services were of no value.

This decision is in accord with one rendered in this State in 1878, and it is no doubt the general rule that the question of malpractice is set at rest by a favorable decision in an action to recover the value of services.

MEDICINE IN THE TIME OF QUEEN ANNE.—In a review of Mr. John Ashton's "Social Life in the Reign of Queen Anne," in a recent number of "The Nation," we find the following:

Medicine was empiricism. In the pharmacopœia given by Mr. Ashton were "live hog-lie," "man's skull," "leaves of gold," "stone of a carp's head," "frogs' livers," "white dung of a peacock dried," with many other remedies equally sovereign. It earned its

fee by purging and bleeding without stint. Its chief processes, whose skill, probably, like that of our spiritualists, was moral, made large incomes—incomes equal to at least \$60,000 or \$70,000 of our day—rode in coaches with six horses, and behaved themselves like ladies. Dr. Radcliffe, the most renowned of them, was sitting over his wine when he received a message from the Princess Anne, who had become somewhat hypochondriac after the death of her sister, desiring him to come at once to see her. He refused to go, and sent back a message that it was all fancy, and that her Royal Highness was as well as any one else. So Mr. Ashton decorously puts it; but the real message, according to tradition, was too coarse to be reported to *her* police. This cost Radcliffe his appointment at court. When the Queen was dying, he was sent for; but the implacable old Turk answered that "he had taken physic, and could not come." There was an outcry against him at the time; in these days he would be torn to pieces. He was always saying the rudest things, and sometimes he met his match. He never would pay a bill without demurring, and he told a pavior who had been mending the pavement in front of his house and applied for the money, that he had done his work badly and covered it with earth to hide it. "Doctor," replied the pavior, "mine is not the only bad work that the earth hides."

Queen Anne, as we know from a passage in Boswell's "Johnson," touched for the King's Evil; strange to say, it appears that she did it in response to a Jacobite challenge to prove her legitimate royalty, and that the result was satisfactory to the public mind; so that the conditions proposed by Renan would seem to have been fulfilled by the performance of a miracle under critical inspection. On the part of Johnson or his parents there must have been a want of faith. With the treatment of children the medical faculty would not have deigned to concern itself. It was such that the race may be said partly to have owed its vigor to a process of natural selection, carried on through a most desperate struggle for existence. The young Duke of Gloucester, the heir to the Crown, having water on the brain, and finding himself unable to get up stairs without help, his royal parents, to cure him of his sickness, shut themselves up with him and gave him a good whipping.

THE eighth session of the International Medical Congress will be held in Copenhagen, from the 10th to the 16th of August, 1884.

THE CHEMISTRY OF THE ELECTRICAL ACCUMULATOR.—With thy attention that is now directed to the storage of electricity, the following description of the chemical action of the Plante and Faure accumulator, as given in a German exchange, will not be without interest. If a plate of lead, coated with a little peroxide of lead, be placed in sulphuric acid, it will soon become covered with sulphate of lead, as a result of local currents between the peroxide and the lead, or by simple chemical solution, so that in Plante and Faure's battery the peroxide is gradually destroyed independently of the main current. This action takes place very slowly, because the sulphate of lead is deposited between the lead and the peroxide, and hence greatly diminishes the local current. If no sulphate of lead were formed, the peroxide of lead would soon be all consumed. The sulphate of lead is subsequently reduced by the hydrogen, forming spongy lead. By repeated charging, the quantity of finely divided substance increases. In a similar manner, if two electrodes that are covered with sulphate of lead be immersed in dilute sulphuric acid, and a current passed through them, one will become covered with spongy lead, the other with peroxide formed from the sulphate. The peroxide formed upon the positive lead plate of the secondary battery becomes covered with a comparatively impenetrable layer, which prevents the further production of peroxide; hence Plante leaves his battery at rest, which favors this formation of sulphate of lead. In this way all the sulphuric acid can easily be taken out of the solution. A considerable quantity of oxygen—more than half—will not be absorbed. According to Kabath, the interior plates of lead foil are rapidly crumbled, but the particles remain hanging between the outer plates.—*Scientific American*.

A TREATMENT FOR PARAPHIMOSIS.—M. R. O'Connor, M. D., writes to the "British Medical Journal" that about a year ago a child was brought to him suffering from paraphimosis. He could not reduce it

by pressure, and was about to cut the stricture, when he was struck with the idea of winding ordinary twine firmly and closely from before backward around the constricted portion of the penis, thus driving the exudation backward until he came to the stricture. On unwinding the twine, he found that the prepuce came forward without difficulty. It has since been repeated, always with success. There is very little pain attending the proceeding. [The procedure is not new.]

THE CLINICAL CHARACTERS OF TUBERCLE IN BONE.—Mr. W. S. Savory ("Lancet," Nov. 4, 1882) remarks that it is curious to see how many striking points of analogy there are between the progress and effects of tubercle in lung and in bone. In the first place, the cancellous texture of bone, which is the seat of tubercle, resembles strongly in physical characters the parenchyma of lung. The structure of both is aptly described as sponge-like, and the resemblance is still more striking when a mass of yellow tubercle occupies the substance of each. In both cases the spongy texture appears to be filled up and rendered solid by the infiltration of the caseous deposit. The resemblance further appears in the halo of inflammation or increased vascularity of varying width which so often surrounds the mass. Still further is the likeness shown in the mode in which the tubercle degenerates. The included tissue is broken down and destroyed until, either by the escape or disappearance of the tubercle, a cavity is left in the cancellous bone corresponding very remarkably to a vomica in the lung.

This likeness is still further extended by the relation of cancellous bone to the neighboring joint, and the relation of lung substance to the pleura. Just as pleurisy is so often set up by the disturbance of tubercle in the lung, so synovitis is often provoked by the disturbance of tubercle in the adjacent bone; and just as empyema is sometimes produced by perforation of the lung-wall and the escape of matter into the pleural cavity, so suppuration in a joint, which is too often destructive, is due to perforation of the articular wall of bone and the escape of matter into the synovial cavity. In either case urgent symptoms are apt to supervene suddenly on comparatively latent mischief.

The variable progress and effects of tubercle in the lung are often repeated with singular resemblance in bone. Just as in lung, so in bone, the history of tubercle is sometimes that of a single formation which passes steadily, with more or less rapidity, to destruction; sometimes that of several smaller ones simultaneously; sometimes, though more rarely, that of a number of successive formations which pass through their stages one after another, leading in this way to a gradually extending destruction of osseous tissue. So, again, there are in tubercle of bone phenomena very exactly corresponding to what Dr. Latham, in the lung and in the cervical glands, has described as mixed and unmixed phthisis. In one class, during the changes which tubercle, after its formation, is prone to undergo, there is only what may be called a necessary amount of inflammation excited in the surrounding texture, such as is just sufficient to accomplish the result of softening and expulsion, and which subsides as soon as this is effected. In another class the inflammation provoked spreads widely and deeply beyond this, and becomes much more severe and extensive than is needful for the mere elimination of the tuberculous matter.

The study of tubercle, if the difficulty would be adequately grasped, must be carried on throughout the whole field of medicine and surgery. For the largest purpose, the land to be explored must be common to both.

MANCEUVRES OF REDUCTION FOR INJURY OF THE SPINE.—Dr. Guermontprez ("Union Méd.," Nov. 11, 1882) relates an interesting case of injury of the spine of doubtful nature in which the greatest relief was derived from manipulation of the injured part, and from extension and counter-extension. The patient fell several yards, striking first on the feet, and then on the buttocks, and had the usual signs of paralysis following injury of the lower part of the spine, together with the most excruciating pain in the lumbar region. This pain was relieved by firm pressure over this point, and more decidedly by extension and counter-extension. The most careful examination failed to reveal the exact nature and seat of the injury. On the day after the accident a fluid tumor of considerable size was found over the lower lumbar region. This was punctured in three places with a bistoury, and a large

quantity of blood evacuated. The patient progressed slowly, but steadily, toward recovery, and, after five months, seemed to be entirely cured. The case is important as showing the remarkable relief which may be derived from efforts at reduction in cases of injury of the spine, provided the efforts are not carried too far.

SPONGE-GRAFTING.—Dr. W. H. Thorndike and Dr. C. D. Homans, of the Boston City Hospital ("Med. Record," Oct. 7, 1882), report four cases of this treatment in different classes of wounds, the only four in which it has been tried at that institution; but the results have not been so remarkably satisfactory as some of those reported in the English journals. They conclude, however, that the treatment is useful in a certain limited class of cases, such as deep, circumscribed ulcers of the leg, which are often followed by adherent cicatrices which readily break down. In these cases the sponge forms a trellis-work through which the granulation springs up from the bottom of the wound, thus preventing the contraction from the edges. The sponges used in grafting should be perfectly clean and thoroughly carbolized. They should then be soaked in dilute acid until they become quite friable, in order that they may be absorbed more rapidly.

THE INVASION OF INANIMATE MATERIAL BY GRANULATION TISSUE.—Dr. C. B. Ball ("Dublin Jour. of Med. Sci.," Oct., 1882) reports four cases which he considers to be as marked examples of the invading of inanimate material by granulation tissue as is ever seen in sponge-grafting. The inanimate material consisted in the first case of a blood-clot, in the second the same, in the third a dry slough the size of a shilling, and in the fourth a large piece of superficially necrosed tibia.

In each of these cases granulation could be seen forming and extending into the foreign bodies; and, as the organization of blood-clot is by no means common, and is even denied by some authorities, the observations are valuable.

THE COUNTY SOCIETY AND THE STATE CODE.—At the January meeting of the Medical Society of the County of New York, forty members being present, Dr. Lewis A. Sayre offered a resolution instructing the society's delegates to the State society to vote for the repeal of the new code of ethics, and to work earnestly to secure such repeal. Dr. Jacobi moved to lay the resolution on the table. On that motion Dr. Sayre called for the ayes and nays, when thirty-one votes were given for tabling the resolution, and nine against it.

THE MEDICAL EDUCATION OF WOMEN IN RUSSIA.—The authorities in Russia are evidently not in favor of the medical education of women. The lecture courses at St. Petersburg have been closed by order of the Emperor, after an existence of ten years. The government has deprived the institution of its buildings, and maintains that the institution had not sufficient means to carry it on properly. Subscriptions were promised, but every obstacle was thrown in the way of their collection. The experiment of female practitioners has evidently been a failure in that country at least.—*Lancet*.

KAVA-KAVA.—This Fijian beverage, lately recommended for gonorrhoea, is thought by Mr. T. M. Kendall ("Brit. Med. Jour.," Oct. 21, 1882) to owe its good effect to its reducing the acidity of the urine. He has found it very useful in cases of enlarged prostate, and credits it with a beneficial action on the mucous membrane of the bladder.

CHOLERA EPIDEMIC.—The Spanish Government has received a telegram, dated December 28th, from their consul at Suez, announcing that cholera has appeared among the pilgrims at Mecca and Medina, and that deaths from the disease at the latter place number ten daily.—*Lancet*.

We understand that Dr. George M. Tuttle, of the State Immigrant Hospital, has been tendered the position of Adjunct Professor of Obstetrics in the College of Physicians and Surgeons, and that he will accept it.

DEATH OF DR. GEORGE M. BEARD.—This well-known neurologist died on the 23d ult., after a brief illness, of pleuro-pneumonia. The news reaches us too late to allow of any statement as to the circumstances of Dr. Beard's untimely death.

Lectures and Addresses.

A CLINICAL LECTURE ON
EXOPHTHALMIC GOÏTRE.

DELIVERED AT THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

By WILLIAM PEPPER, M. D., LL. D.,

PROVOST AND PROFESSOR OF CLINICAL MEDICINE.

GENTLEMEN: I shall ask your attention to-day to an interesting and marked condition of exophthalmic goitre in the male. I shall first briefly give the history, and then ask attention to the pathology of this affection.

This man is thirty-two years of age; lives in Mifflin County, of this State; a teamster by occupation; has not worked very hard, but has been exposed to all kinds of weather; has been temperate in the use of liquor, but an immoderate consumer of tobacco, smoking almost constantly and chewing a great deal. He has had no anxiety nor nervous strain of any kind to impair his health; no venereal history. His family record is good; he had the common fevers of childhood, but since then has been well and strong, and not at all nervous. For the past ten years he has noticed a little shortness of breath on exertion, without cough and without any disturbance of urine. For the last eighteen months has been nervous, could not sit still, was constantly shifting his position, and could not fix his attention on any subject. With this there was increased shortness of breath. Sixteen months ago he had a bad fall, which made his condition worse. Nine months ago he observed that the right side of the thyroid gland was swelling. The left side began to enlarge one month later. The enlargement gradually increased. The eyeballs began to be prominent six months ago. Two months ago palpitation of the heart, which had existed to some extent before, became pronounced, and all the symptoms grew worse. He has not been able to sleep well, and his digestion is impaired. He passes large quantities of light-colored urine; he has also, for the past ten or twelve years, had a tendency to looseness of the bowels, having one or two stools of mush-like consistence each day. In June last, soon after these symptoms began, he had an attack of dysenteric diarrhœa, frequent stools mixed with mucus and blood.

The diagnosis of this case is perfectly simple. We have great rapidity of the heart's action (150 in the minute), irregular pulse, no organic murmur, slight enlargement of the heart, great increase in the size of the thyroid gland, which throbs, pulsates, is the seat of a thrill and of a strong murmur, and there is slight prominence of the eyeballs. He is nervous, pale, anæmic, and dyspeptic. These are the symptoms of exophthalmic goitre—that is, goitre or bronchocele with protrusion of the eyeballs. The latter symptom is not marked here. This disease is also known by the names of two men who described it independently of each other, but about the same time—Graves, of Dublin, and Basedow, of Germany. It is, therefore, often spoken of on the continent as Basedow's disease, while English writ-

ers call it Graves's disease. The name exophthalmic goitre gives two of the prominent symptoms. The three marked changes in this disease are cardiac derangement, which shows itself in rapid, irregular action of the heart, goitre, and prominence of the eyeballs.

Exophthalmic goitre is more common in women than in men. In a memoir on this subject which I read before the Medical Society of Pennsylvania, in 1879, I stated that out of sixty-eight cases of this disease fifty-six were females and only twelve were males; that is, the proportion is about eighty per cent. of females to twenty per cent. of males.

I wish to-day to speak more of the pathology and the treatment of this disease than of the symptoms, for I hardly think that you can make a mistake in diagnosis. The only conditions in which you might fail to recognize the affection are where a person with anæmia and some overaction of the heart has ordinary goitre; and in the early stage the disease may be overlooked from the fact that the thyroid enlargement is not great and the protrusion of the eyeballs not marked. Anæmia with ordinary goitre will be distinguished from the disease under consideration by the condition of the thyroid. In the former it is enlarged but firm, it does not pulsate, there is no thrill, and it is not the seat of a hum.

The pathology of this disease is now, I think I may say universally, recognized as dependent upon a deranged action, a deranged functional activity, or actual organic disease of the cervical ganglia of the sympathetic and the cardiac plexus of nerves. These nervous centers govern the action, the latter of the heart, and the former of the branches of the carotids; so that, the functional activity of these centers being impaired, there is a state of dilatation and overaction of those parts of the circulation which they control. This is shown in the heart by great excitement and irregular action, and a tendency to dilatation of the organ. It is shown in the branches of the carotid by excessive dilatation, especially of the thyroid artery, by the large amount of blood which passes through them, and by the pulsation and the local throbbing. Some have said that in this disease there is always organic lesion of the nerve centers which I have mentioned, but this is not true. There sometimes is, and it has been found on post-mortem, but I have made autopsies where it was absent; again, in so many cases the patients get well and the symptoms disappear that it is clear that organic disease of the nerve centers could not have existed. We must, therefore, say that while in some cases there is organic disease, a degeneration of the nerve cells or fibers, the affection is, in a greater number of instances, due to impaired functional activity dependent on depressing causes and not associated with any positive organic lesion.

The depressing causes which give rise to exophthalmic goitre are those which act directly upon the vaso-motor system of nerves—that is, causes of an emotional character, as sudden fright, severe shock, prolonged strain, anxiety, and care; but in a still larger number of cases the causes which give rise to the disease are the general depressing causes which impair nutrition, produce anæmia, and, with this, excessive sensibility of the nervous system. We are

all familiar with the nervous phenomena which manifest themselves in various ways in different persons as the result of depression, lowered tone, and advanced anæmia. More and more clearly do we recognize the dependence of the nervous phenomena on that state; so it is here; you will find that perhaps the most fruitful cause of exophthalmic goitre is a condition of deranged nutrition.

In the paper to which I have alluded I have reported some interesting cases, one or two of which I shall read.

"Miss A., aged twenty, although generally healthy, had always been exceedingly nervous. She had always been used to eating unwholesome food, candy, cake, sugar, with quantities of tea and coffee, and insufficient food of a plain, nourishing character. In the summer of 1876 she attended camp-meeting, was subjected to great excitement, and much exposed to vicissitudes of weather. Severe diarrhœa resulted, and was not checked. No attention was paid to diet or the avoidance of exposure. The stools were frequent, ten to twenty on some days, thin, whitish, and fetid. This condition became chronic. Soon afterward, in September, 1876, she noticed palpitation of the heart, with dyspnœa and enlargement of the thyroid gland. She grew weak, and lost flesh rapidly. She became extremely nervous and very lachrymose, so that she wept on the slightest cause. Her temper was not particularly changed, except that she became more petulant. Frequently an ordinary remark quietly addressed to her would cause a burst of tears. By Christmas, 1876, exophthalmus began, and rapidly increased until her eyes were very prominent. She continued in this condition, despite medical treatment, until October 20, 1877, when I first saw her. The diarrhœa had persisted, with the same character of stools. Menstruation had ceased five months previously. She had lost much flesh, her weight being scarcely ninety pounds, whereas fourteen months previously it had been one hundred and forty pounds. Her appearance was shocking on account of the extreme exophthalmus and the very large goitre. She was unable to close the eyelids. The action of the heart was constantly rapid, and frequently as high as 175 to 180. There was a soft anæmic cardiac murmur over the base. The thyroid gland pulsed very strongly, and was the seat of a strong, diffused thrill, and of a loud, shrill murmur. When the stethoscope was applied over the temporal fossa to the anterior part of the parietal bone on either side, a distinct, high-pitched murmur was audible. She made a rapid recovery, gaining sixty pounds in nine months."

Here is another good case: "Mrs. — was sent to me in August, 1878, by Dr. Birnie, of Maryland. She was about twenty-two or twenty-three years old, and had recently been married. From 1870 to 1873 she resided in an unhealthy locality, and there began to have occasional spells of feverishness, which was soon accompanied with diarrhœa. These attacks would usually last three or four days at a time. There does not seem to have been any fully developed malaria. After returning to her home, which was in a healthy mountain district, she continued to have spells of diarrhœa, with feverishness. She did not, however, lose much flesh or strength. In the spring of 1876, enlargement of the thyroid gland and prominence of the eyeballs was first noticed. At

that time she weighed one hundred and four pounds. In June, 1877, a severe attack of diarrhœa began, and continued until the following October. During this time she rapidly lost weight until she reached sixty-eight pounds. The enlargement of the thyroid gland and the exophthalmus also increased rapidly, and attained proportions as great as at any subsequent period. After the cessation of the diarrhœa in October, 1877, she began to gain weight, and during the ensuing winter reached one hundred and eight pounds. There was, however, no improvement in the condition of the eyeballs or of the thyroid gland. She continued weak, also, with marked excitement of heart's action.

"Diarrhœa returned in June, 1878, but for some time previously she had been losing flesh. By the time I first saw her, in August, she weighed less than seventy pounds. The character of the discharges in all the attacks of diarrhœa was similar—thin and watery, with particles of undigested food, but without either blood or pseudo-membrane. There had been very frequent complaints of pain at the lower part of the abdomen. In addition to the foregoing symptoms, there were for several years quite frequent and copious hæmorrhages from the nose. Menstruation had always been scanty and irregular, and lately had been absent for a number of months; it occurred twice in 1877, and three times in 1878. During the summer of 1878, œdema of the ankles frequently appeared toward evening.

"On examination, in August, 1878, her condition appeared very alarming; she was extremely emaciated and feeble. The immense protrusion of the eyeballs and the enormous enlargement of the thyroid gland gave her a shocking appearance. She was unable to cover the cornea, but no inflammation had occurred. Emaciation was extreme; her weight did not reach seventy pounds, and the skin and mucous membranes were bloodless and slightly sallow. The tongue was tremulous, red, and smooth. The appetite was capricious and somewhat abnormal. The bowels were moved frequently from four to eight times in twenty-four hours, the dejections being of the character I have described. The respirations were frequent, and increased by the slightest exertion. The pulse was weak, small, and frequent; in the sitting posture, it averaged 140. Exertion brought on severe palpitation. The heart sounds were sharp and feeble, with strong hæmic murmurs at the base and along the pulmonary artery. The carotids throbbed excessively, and the thyroid was the seat of strong diffused pulsation and thrill, with loud humming murmur on auscultation. No venous hum could be heard on ausculting the temples. There had been frequent epistaxis of late. The feet and ankles were œdematous. The urine was pale, of low specific gravity (1009–1010), but contained no albumin." The improvement in this case was steady and rapid. Menstruation became regular in March, 1879. In May, 1879, the thyroid was greatly reduced in size, she was bright and active, and her appearance was so much improved that she would not have been recognized by any one who had first seen her in August, 1878.

I want to call attention to the fact that, as regards the cause of exophthalmic goitre, we very often have no history of emotional disturbance, but only the ordinary causes of

deranged nutrition which induce anæmia and excessive nervous mobility. These are often associated with indigestion and the loss of good primary assimilation of food, usually from subacute gastro-intestinal catarrh. I have seen exophthalmic goitre follow, in a few weeks, a sharp attack of gastro-intestinal catarrh, but more frequently it comes on where there has been slight inflammation continued for a long time, and where the crisis of the blood has been gradually impaired and weakened. In this weak state any depressing cause will act upon the nervous system, inducing excessive nervous mobility and sensitiveness. This long-standing inflammation will also act as a source of reflex irritation upon the weakened nervous system and gradually induce a state of reflex paralysis of these centers. We are all familiar with the reflex paraplegia which follows long-continued cystitis, where the lumbar centers have been exhausted by the reflex irritation of a bladder in a state of chronic catarrh. We are all familiar with the various forms of paralysis coming on in cases where the nerve centers have been subjected to long-continued irritation from some peripheral lesion. In chronic intestinal catarrh there is long-standing irritation of the peripheral filaments of the pneumogastric and other nerves supplying the mucous membrane of the stomach and intestines, which, by reflex action, affects the centers with which these nerves are connected—that is, the cervical ganglia of the sympathetic and the cardiac plexus. This disease is frequently associated with gastro-intestinal catarrh. To this may be added irritation of the sexual organs; thus, in women we frequently find chronic ovarian irritation with chronic catarrh of the uterus. This may take the place of the intestinal affection. If it is associated with the chronic intestinal catarrh, we have, of course, a double effect of deranged nutrition upon a sensitive nervous system. You see an instance of this in the latter of the two patients whose history I have given. She had uterine catarrh, ovarian congestion, irregular menstruation, and chronic intestinal catarrh. No wonder that in such a patient there was such an intense development of all the phenomena of this disease. If this be true, if this be the history as regards cause, the indications as regards treatment are very plain.

It will at once be seen that this disease is not to be treated empirically, or by any single drug. You will find in many of your text-books, I am sorry to say, that this author recommends ergot; this one, the bromides; this one, digitalis; this one, iron, as a treatment for exophthalmic goitre. There could be nothing more irrational than this. We could not have a better disease than this to impress upon us the lesson that, long before we come to prescribe any drug in a chronic disease of this kind, we should study the individual peculiarities of that disease, and recognize what there may be about that patient in the way of bad hygiene to be corrected, bad habits to be abandoned, improper diet to be modified, unhealthy residence to be changed, or local irritation to be removed. While by giving certain remedies you may hold some of the prominent symptoms in subjection, you will allow the fundamental condition which produces the disease to go unchecked, and the patient does not get better. The only rational and successful way of treating any such condition as this is to first

study critically what can be done by hygiene, regimen, and diet, before we come to the question of what drugs can be prescribed with advantage. I may seem to dwell upon a self-evident proposition. If it seems so to you, let me dispossess your minds of any such notion. It is the hardest thing to bear in mind in practice. It is difficult for us to possess the incessant freshness of mind that when we see a new patient we shall enter into a careful study of these old, simple matters, and avoid being drawn into specific methods of treatment. A patient who had been under the care of a most excellent physician came to me this morning, and, when I spoke to her on this subject, she said: "Why, he never spoke to me about my diet. He laid no injunctions on me. I have taken enough medicine to fill a room, but I am no better." The question was solely one of diet, a case of gastro-intestinal catarrh, in which nothing but hygiene and diet would do any good.

In the treatment of this disease, the first thing to be done is, of course, to remove whatever local condition we may find. I should, in the first place, recommend absolute rest in bed, so as to place the nervous system at rest; to avoid exposure to changes of temperature and the like, and prevent all drain upon the nutrition until we have relieved the gastro-intestinal catarrh, and have rendered the alimentary canal capable of absorbing and assimilating food. This question of rest is an exceedingly important one. It need not in all cases be absolute. Rest, varied with a graduated amount of out-door exercise, is usually the ideal regimen. I shall allow this man to lie in bed twenty-two hours out of the twenty-four. He will walk out-doors for fifteen minutes every morning and afternoon, and spend an hour or two around his room.

In the next place, I shall put him on a carefully restricted diet. His present weight is one hundred and thirty-eight pounds; in February he weighed one hundred and seventy-five pounds. I shall begin with a diet such as this: In the morning, a glass of warm milk. For breakfast, fine ground hominy grits, with a little cream or milk, a glass of milk and hot water, and a bit of stale bread. At ten o'clock a glass of warm milk. For dinner, a piece of beefsteak, with stale bread and a little water—no ice-water. At three o'clock, a glass of warm milk. At supper, more thoroughly cooked hominy grits, with milk and hot water, and stale bread. At bed-time, another glass of warm milk. In the course of the day he will receive three small meals and four glasses of milk.

This man's tongue is a little coated posteriorly, and is denuded of epithelium. The gastro-intestinal irritation has lasted so long that I have no doubt that, if we could look into this bowel, we should find enlargement of the follicles of the mucous membrane, constituting a slight but extensive subacute intestinal catarrh. I know of no drug which compares in its beneficial action upon this condition of catarrhal irritation of the gastro-intestinal canal with nitrate of silver. I do not think that there is any drug to be mentioned with it. This condition of gastro-intestinal catarrh enters as a factor in so many different diseases that you frequently hear me prescribe nitrate of silver. I think that the more you use small doses of this drug in catarrhal con-

ditions the more you will value it. I have come to regard it as one of the most commonly needed, one of the most generally applicable, and one of the most precious remedies in existence. I rank it with opium, quinine, iron, and arsenic, as among the great resources of our art. If it is properly administered in varying doses, and different combinations, at different times and in conjunction with different forms of diet, results can be obtained which will, I think, gratify you the more, the more faithfully you use it. I shall give this man one fifth of a grain of nitrate of silver, with one tenth of a grain of powdered opium, in a hard pill-mass, made with a little gum tragacanth, three times a day, on an empty stomach; that is, about one hour and a half after one of those small meals before described. For the present I should recommend no other treatment.

When I find that his stools are solid and the food is properly assimilated, I shall use iron. This remedy is usually needed. Scarcely ever will you fail to find *anæmia* in exophthalmic goitre; consequently, you will find that iron in large doses often exerts a powerful effect upon these exhausted nerve centers in this as in many similar conditions, so that, even where the external evidences of *anæmia* are not prominent, iron in large doses has often a tonic effect upon the nerve centers. Of course, in proportion as actual *anæmia* exists its use is the more imperative. It must be administered with a due regard to the condition of the stomach and bowels, and an easily digested preparation must be employed. In regard to the preparation of iron to be selected, the experience of each practitioner, I suppose, dictates the form which he prefers. Some use the tincture of the chloride freely diluted; this is one of the most valuable preparations. Others use the pill of the carbonate; others, one of the soluble salts—as the lactate, the potassio-tartrate, and the citrate. The potassio-tartrate and the citrate are rather more apt to irritate the bowels than the pill of the carbonate or lactate, or even than the tincture of the chloride. Where there is considerable irritation of the mucous membranes, I know of no preparation of iron that is so acceptable as dialysed iron. Dialysed iron has been in the fashion, but is now forgotten; like all reigning favorites, it is soon deposed and a new one put in its stead. Three or four years ago every one was taking dialysed iron. As you know, it is prepared by dialysing a solution of a salt of iron through an animal membrane; the solution of iron being on one side of the membrane and a saline solution on the other, the acid is drawn from combination with the iron, leaving the latter, as near as may be, in its virgin state. It is exceedingly prone to change, and, when exposed, throws down a gelatinous precipitate. It is almost tasteless, does not act upon the teeth, and is very acceptable to the stomach. After it had been used to a great extent, question began to be raised as to whether it did any good; then, after everybody had been using it, everybody discarded it. I must confess that dialysed iron has given me excellent results. Read what I say in regard to it in the notes of the case of Miss A.: "After the diarrhoea was controlled, dialysed iron was given. All of her symptoms improved rapidly, and she gained flesh quickly. She soon wearied of the restricted diet, and about the middle of Sep-

tember she stopped all treatment and returned to a mixed diet. Diarrhoea soon returned, and she rapidly lost flesh; and all her symptoms—the cardiac excitement, goitre, and proptosis—again increased. On February 7, 1878, I saw her again, and directed a return to a similar diet, and to the use of silver and opium for a time, to be followed by digitalis and dialysed iron. The diarrhoea was again readily checked, and rapid improvement immediately commenced, and continued without interruption. The dialysed iron was increased gradually from ten to forty drops, and its effects were definite and gratifying. If suspended for even two or three days, she asserted that she missed its tonic influence. Her gain in weight was as follows: From February 7th to March 19th (forty days), from one hundred to one hundred and twenty-five pounds; from March 19th to June 20th (ninety-three days), from one hundred and twenty-five pounds to one hundred and forty-two pounds—a total gain from February 7th of forty-two pounds. She seemed to make blood and flesh so rapidly that at that time the dose of dialysed iron was reduced to ten drops. She increased to one hundred and fifty pounds in the course of six weeks, having gained sixty pounds in all within a period of nine months. There was a correspondingly rapid improvement in the nervous symptoms. She ceased to be lachrymose, and lost, to a great extent, the morbidly excitable, impressionable character she had before presented. Her color became healthy. The prominence of the eyes disappeared almost entirely before June 20, 1878, and, when I last saw her, December 14, 1878, it had not returned. The enlargement of the thyroid gland had also gone. By June no hæmic murmur could be heard over the heart, neck, or temple; and all pulsation, thrill, and murmur had gone from the region of the thyroid gland. Menstruation returned in May, 1878, after an absence of fifteen months, and subsequently continued regular. The pulse still continued somewhat too rapid, and was readily accelerated by any excitement. Up to December, 1878, she still continued a diet chiefly of milk and farinacea, with but little meat, and no tea or coffee."

I have seen such good results from the use of dialysed iron that I still continue to employ it where the gastric digestion is pretty fair. It is evident that this preparation requires to come in contact with some acid in the gastric juice which will form it into a soluble, assimilable salt of iron. It is probable that, in the cases in which it has failed, the stomach was in a deranged condition, so that the iron was precipitated and not formed into a soluble salt.

I shall, then, as soon as this man's bowels are in a good condition, give dialysed iron, in doses of ten drops in two ounces of water, three times a day after his milk. The dose of iron will be gradually increased to forty drops.

I come next to speak of the substances which are used for the control of the special symptoms of the disease. The first of these in value is digitalis, without which you will treat no case of exophthalmic goitre with complete success. It is given in the form of the tincture, or the powder in pill form, or the infusion of the fresh leaves, or as granules of digitalin. Digitalis prevents excitement of the heart, and indirectly allays nervous irritability and alleviates dyspnoea.

Ergot has been strongly recommended on account of its

influence on the muscular walls of organs, for we have here a tendency to cardiac dilatation, and dilatation of the blood-vessels, with weakening of their coats; but ergot acts directly upon the muscular elements of these parts, and not upon the depressed nerve centers which govern and control the circulation in them, while rest, good food, iron, and digitalis act more especially upon these centers, and are, therefore, more suitable than ergot. It has given good results in some cases. I, however, use it very rarely, and never resort to it until the deranged digestion is controlled; and even then it will often cause nausea and vomiting.

The bromides are very useful. There is an exaggerated mobility of the nerve centers; a lachrymose or even a maniacal tendency, and in general a perverted temper and exaggerated sensitiveness, which are indications for a sedative; so that the use of the bromides frequently forms an important part of the treatment. They may be combined with digitalis and ergot in the form of sodium or potassium bromide.

Lastly, I shall mention the importance of galvanizing the cervical ganglia of the sympathetic by passing a slowly interrupted, mild current through these glands. This may be used in conjunction with the other treatment.

I shall treat this man in the manner I have mentioned. I shall have the blood corpuscles counted, and in six weeks shall show you the result.

A LECTURE ON

THE FREQUENT REPETITION OF DOSES.

DELIVERED AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

By A. A. SMITH, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF CLINICAL MEDICINE.

GENTLEMEN: I propose to direct your attention this morning to the subject referred to at my last lecture, namely, the frequent repetition of doses. This subject is a very important one, and one regarding which it is very difficult to establish any arbitrary rules. In the case of chronic diseases, where it is necessary to continue the treatment for a long time, the plan of administering the medicine in larger doses at intervals of five or six hours is probably the best one which can be adopted. For example, if you were prescribing some preparation of iron in a case of anemia, it would be unnecessary to give it oftener than three times daily. Again, in certain cases it may be desirable to produce the full effect of the drug at a single dose, as in the administration of a cathartic, or of quinine to reduce temperature.

In other cases, however, it is desired, in administering medicinal remedies, to keep up their continued effect, and the question arises, whether we can accomplish this purpose better by giving them in smaller doses at frequent intervals than by giving them in large doses at much longer intervals, the total amount of the drug in the end being, perhaps, the same in either case. It is a fact with which you are acquainted that certain drugs become absorbed and produce

their effect upon the system in a very short time, and they may also be eliminated very rapidly, while others act slowly and are eliminated after a longer interval.

It is not my intention this morning to deliver a scientific lecture; I shall make certain statements based upon clinical facts for which I shall not attempt to give any explanation.

The first drug to which I would call your attention in connection with the subject of the lecture is the chlorate of potash. It may not be unknown to most of you that this drug has at times been administered in sufficiently large doses to produce a dangerous inflammation of the kidneys. Special attention has been called to this fact by Dr. Jacobi, of this city, and also by other authors. This danger can be avoided by administering the drug in small doses frequently repeated. In writing the prescription, a teaspoonful of the solution may be made to represent as much of the drug as you wish to give; or, if it be in a more concentrated form, the patient may add water to it. Grain doses given every half-hour in scarlet fever, diphtheria, tonsillitis, etc., will produce the same results as larger doses, without the danger of the evil effects resulting from the accumulation of the drug in the system, as sometimes happens when it is administered in the ordinary way. Indeed, I believe they will produce better results upon the throat inflammations.

For the treatment of neuralgia, croton chloral has for a long time been given in large doses, as from five to eight grains, repeated every two hours, until fifteen grains are taken. But allow me to suggest what I consider a better mode of administering the drug—that is, to give a grain of it, prepared as you please, either in liquid or pill form, every half-hour until the neuralgic symptoms are relieved. A solution of which a teaspoonful represents a grain of the croton chloral may be made, having scarcely any of the bad taste which usually belongs to this medicine when given in large doses. I may here remark that one of the important advantages connected with the frequent repetition of doses is the fact that the medicine may be so largely diluted with water or other vehicle as to be rendered comparatively tasteless, and harmless to the mucous membrane of the stomach.

You will often be called upon to treat very obstinate cases of urticaria, and you will be put to your wits' end to know what to do. The plan ordinarily suggested is to give alkalis, as the bicarbonate of sodium, or magnesium; but, if you will give the patient two grains of the salicylate of sodium every hour or half-hour, you will usually be enabled to effect a cure even in obstinate cases, except those of a chronic nature. Two grains of the salicylate of sodium administered in a teaspoonful of water is almost tasteless, and may be given without producing disturbance of digestion. Urticaria is often caused by the administration of full doses of balsam of copaiba in cases of urethritis, or inflammation of other mucous membranes, and it may seem strange to you when I make the statement that a single drop of the same drug given every half-hour will sometimes control urticaria. I have no explanation to offer, but I make the statement not alone upon the authority of others; I myself have often observed the efficacy of the treatment, although not so frequently as in the treatment by the salicylate of sodium.

Fowler's solution, or the liquor potassii arsenitis, half a drop given every half-hour for six or eight doses, will often relieve the vomiting which occurs after a debauch. It will also relieve the morning vomiting of drunkards, and is of decided benefit in the sympathetic nausea and vomiting of pregnancy.

Jaborandi has been given in large doses with a view to exciting perspiration in cases of Bright's disease, but the very serious objection has been found to its administration in this manner, that it sometimes has a very depressing effect upon the heart's action, resulting in some cases fatally. Now, five- to ten-minim doses of the fluid extract of jaborandi given every hour or half-hour will produce marked perspiration without causing any unpleasant effects upon the heart. I sometimes combine with the jaborandi the tincture of digitalis, with a view to counteract any possible evil influence which the former drug may have upon the heart. So dangerous do I consider large doses of jaborandi that I often hesitate long before administering it, especially in the uræmia of the puerperal state.

You will please remember that the amount of the medicines administered is not so small as you may at first suppose, especially if you take into consideration their strength and the frequency of their repetition.

The next preparation of which I shall speak is a solution of the sulphate of atropine, one one-hundredth of a grain in a goblet of water, a teaspoonful of which shall constitute a dose, amounting in all to about sixty doses. Now, you will often be called to see cases of supposed croup, but which, in the majority of instances, prove to be cases of false croup of a reflex origin. Ordinarily, you will be able to relieve these patients by giving them a teaspoonful of this preparation every hour. It is possible the remedy acts slightly as a stimulant of the respiratory center; it is also possible that it has some influence upon muscular contraction or relaxation; at all events, clinical experience proves that it is of benefit in these cases. The dose may be repeated every hour or half-hour, according to the severity of the attack. If the child's face begins to flush and show signs of the physiological effects of the drug, the dose can be reduced in frequency. It should be remembered that when thus administered the equivalent of a full dose of the drug will soon be reached. Do not forget in these cases to give an emetic if there is anything in the stomach which may be causing the spasm, or a cathartic if there be reason to suspect intestinal disturbance as the cause.

The bromides are largely used in the treatment of the nervous and febrile disturbances of children, but an objection to them is the fact that the little patients do not take them readily, because of the taste; the bromide of sodium is, perhaps, as little disagreeable as any of the preparations. This objection can be avoided by giving small doses frequently repeated; for instance, a few grains dissolved in half a tumblerful of water, a teaspoonful representing a half-grain, or a grain even, administered every ten or fifteen minutes. When given in this manner, the bromides often prove of great benefit in the nervous disturbances arising from dentition and other causes, and in relieving the fever which, in children, usually attends a slight degree of excitement of any kind.

I have seen an elevation of the temperature in children where it could not be traced to any other cause than the excitement incident to their afternoon play. A temperature which might indicate a sickness of considerable gravity in the adult, if it occur in a child may be of comparatively little importance. In such cases the bromides, administered in small doses, say a grain or two at intervals of ten or fifteen minutes, will often prove of great benefit.

I began the use of some of these remedies administered in this manner on the recommendation of others, and I must say in a somewhat skeptical frame of mind, thinking that the effect which they produced was probably due to the moral influence upon the patient, or that it had no foundation in fact, it being a mere coincidence that the drugs were administered at a time when the patients would have recovered in the absence of any treatment; but, having seen benefit follow their administration repeatedly, I concluded they must have a wider range of usefulness, and began to use them much more frequently.

You will often meet with children of a nervous, excitable frame of mind, who are, perhaps, naturally of a sensitive, nervous temperament, who are disturbed by the slightest noise, and are unable to go to sleep before ten or eleven o'clock at night. In such cases you will find it necessary to give a nervous sedative. An excellent effect will be produced by chamomilla in some one of its forms, as the tincture, administered in minim doses, every fifteen or twenty minutes. It is tonic as well as sedative. It is a better sedative in such cases than the hydrate of chloral, which is liable to affect the digestion. It is harmless when given in larger doses. Put a teaspoonful into a half-tumblerful of water, and let the child drink it freely.

One of the most important remedies which can be administered with great benefit in frequently repeated doses is ipecac. You are aware that a teaspoonful of the syrup of ipecac is likely to produce emesis; but it is also a fact, regarding which I was at first quite skeptical, that a single drop of the wine of ipecac will often arrest obstinate vomiting. It should be repeated every ten or fifteen minutes. When administered in this manner, I have often known it to relieve vomiting from different causes, among which are pregnancy and subacute gastritis. Children often vomit from very slight causes, and are liable to suffer from diarrhoea and vomiting which have no other assignable cause than disturbance of digestion. A single drop of the wine of ipecac, repeated every fifteen or twenty minutes, will often produce the most marked relief, both from the vomiting and from the diarrhoea. Administered in this manner, the drug is not nauseous, and is easily taken.

I now make a statement, upon the authority of Trousseau and his enthusiastic successor, which may appear to you, as it once did to me, incredible—viz., that one sixtieth of a grain of calomel taken every hour for ten or twelve hours will relieve the headache of syphilis occurring at night. I have administered it in one-fortieth-grain doses in this manner and have obtained the results which they claimed for it, but I have not yet tried it in sixtieth-grain doses. The relief was very marked by the second or third night. It is not intended to take the place of iodides which are given in such cases.

Doubtless the calomel, when administered in such small doses, is all taken up into the system.

Nursing children often vomit or regurgitate their food; this has been relieved repeatedly in my experience by giving them a teaspoonful of a solution of one grain of calomel to the pint of water every ten or fifteen minutes. In order to dissolve it, the calomel should first be put into an ounce of lime-water, and then into the pint of pure water. One twenty-fourth of a grain of mercury with chalk, administered every fifteen or twenty minutes, is often of great benefit in the vomiting and non-inflammatory diarrhœa of children. Where the diarrhœa is accompanied by mucous passages, indicative of a certain degree of inflammatory action, or enteritis, benefit will be derived from the administration of one teaspoonful of a solution of bichloride of mercury (corrosive sublimate), one grain to the quart, every hour. The dose may seem very small, but it must be remembered that the dose for an adult is only one sixtieth to one thirtieth of a grain, and, when administered in this manner, the full dose for a child is reached within a few hours.

Another extraordinary statement, which at first seemed to me to be fabulous, and may seem so to you, but which, nevertheless, you will find to be based upon clinical facts: Put a grain of tartar emetic into one quart of water; teaspoonful doses of this solution every half-hour will prove effectual for the relief of the wheezing and cough accompanying a slight bronchitis in children.

A single drop of the tincture of *nux vomica* given every ten minutes will often produce most marked relief in sick headache not of a neurotic origin. It should be given immediately after or soon after meals.

It is well known that cantharides, when given in large doses, is liable to cause inflammation of the urinary tract; but it has been found that a single drop of the tincture every hour will in many cases relieve vesical catarrh.

You probably have heard that digitalis has been used in cardiac disease. Certainly if you have not heard of it you will, and, if you have already heard of it, you will hear of it again, particularly at the clinics. Ordinarily, it is administered in considerable doses only three or four times a day; but I do not hesitate to say that the frequent repetition of small doses will produce much more benefit than larger doses at longer intervals. A single drop of the tincture of digitalis, given to a patient suffering from symptoms due to organic heart disease when digitalis is indicated, administered at intervals of an hour or half-hour, according to the severity of the symptoms, will often give greater relief than larger doses, and without liability to ill effects.

For the diarrhœa of children, accompanied with slight inflammation, straining, and the passage of jelly-looking matter, but not true dysentery, five drops of castor-oil, given every hour in water with sugar and gum, is an excellent remedy.

A gentleman in this city, of authority in the specialty of venereal diseases, says he has given greater relief in a short time, in cases of orchitis and epididymitis, by the administration of two-minim doses of the tincture of pulsatilla every hour than by any other mode of treatment. I can testify to the great benefit derived from the drug ad-

ministered in this manner in dysmenorrhœa not of a membranous, obstructive, or neuralgic character.

One of the most distressing symptoms from which many women suffer at the menopause is flatulence, and a sensation of fluttering or palpitation at the pit of the stomach, an effectual remedy against which is the extract of calabar bean in one-fiftieth-grain doses, repeated every half-hour for six or eight doses. It may be repeated in the same way after stopping it for three hours.

In cases of amenorrhœa not dependent upon anemia, benefit may be derived from minim doses of the fluid extract of ergot administered every half-hour for five or six hours the day before the flow should begin, and again on the day on which it should occur. Contradictory as it may seem, when administered in the same manner the fluid extract of ergot is of benefit in cases of excessive menstruation.

Aconite is one of the drugs to which you will probably have occasion to resort frequently when you enter upon the active practice of medicine. It has for a long time been used in quite small doses, but not so frequently repeated as it might be with benefit. There are many cases of febrile movement, with dry, hot skin, a full, bounding pulse, the mucous membrane of the throat and nose probably dry—cases in which the febrile movement is not the commencement of one of the continued fevers; the tincture of aconite, one third to one half a minim given every fifteen minutes, will be found of decided benefit. Visiting the patient shortly after the commencement of this treatment, you will often find him in a little perspiration; the medicine may then be administered at longer intervals, every half-hour or longer, according to the indications. The tincture of aconite, administered in a similar manner, is also useful in cases of commencing so-called cold in the head. It is likewise useful in cardiac hypertrophy with palpitation, severe headache, and disturbances of the nervous system due to increased force of the heart-beat.

Two minims of the tincture of hamamelis every half-hour will often control hæmorrhages. I was at first inclined to look upon this statement with a great deal of distrust, but I have since tried it in cases of hæmorrhage from the nose, from the uterus, and in the hæmorrhage from hæmorrhoids, and have found it of great benefit.

The tincture of belladonna in minim doses, given every half-hour, is a good remedy in cases of nasal catarrh, and bronchitis accompanied by free secretion. You should cease to give the drug for a while after eight or ten doses have been administered, as it is less quickly eliminated from the system than the other medicines of which we have already spoken. In cases of pulmonary œdema with failure of heart power, belladonna thus administered is of benefit in retarding the exudation of serum, and in overcoming the failure of heart power.

Two grains of the chloride of ammonium, combined with ten or fifteen minims of the tincture of cubebæ, given every half-hour, oftentimes controls acute pharyngitis and superficial inflammations of the other tissues about the throat. For inflammation of the throat dependent upon a gouty diathesis, add to this mixture ten minims of

the ammoniated tincture of guaiac, and administer every hour.

In the headache of migraine, one grain of the citrate of caffeine given every half-hour will often produce most marked relief.

In neuralgias about the face or head, three-minim doses of the tincture of gelsemium every half-hour will often act almost miraculously and leave no ill effects.

For certain kinds of headaches (especially those which are periodical and not of malarial origin), fifteen-minim doses of fluid extract of guarana given every fifteen minutes will very frequently relieve. If it does not relieve in four doses, increase the dose to thirty minims.

Original Communications.

ON EYE TROUBLES WHICH MAY BE ERRO- NEOUSLY ATTRIBUTED TO LESIONS OF THE BRAIN AND NERVOUS SYSTEM.*

By HENRY D. NOYES, M. D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOTOLOGY IN BELLEVUE HOSPITAL MEDICAL
COLLEGE.

MR. CHAIRMAN AND GENTLEMEN OF THE SECTION: The remarks which I have to offer this evening, and which are presented at the request of our chairman, are hastily thrown together, and are simply the expression of views and opinions long matured in my own mind. They will be illustrated by a few cases bearing upon special points. The connection which subsists between diseases of the eye and other parts of the system, especially the nervous system, is coming to be more thoroughly appreciated since the ophthalmoscope has proved its capability of giving us more extended information than relates to the eye alone.

This instrument has been employed extensively in the hands of neurologists and general physicians. What I have to say is in no sense to its disparagement; on the contrary, it should be used more freely than at the present time, both in the hospitals and general practice. But my remarks are intended as a caveat, to assist the general practitioner in avoiding mistakes, viz.: First, that of attaching to certain things seen in the eye more importance than they deserve; and, secondly, I propose to call your attention to a considerable class of cases in which functional disturbances are sometimes mistaken for difficulties of the nervous system, whereas they originate from the eye. When we look for evidence in the eye of a diseased condition of the optic nerve, we note its color, its transparency, its definition, etc.; and we note the retina, as to its transparency and condition of its blood-vessels.

Now, the optic nerve varies, to a degree which is not properly appreciated, as to its shade and color; and if we were to draw inferences from its vascularity, in reference to possible trouble of the brain, we would be very likely to fall into error. The truth is, that acute inflammations of the

brain do not quickly exhibit themselves in the optic nerve; when they do, the trouble usually lies at the base of the brain, as meningitis or fractures. On the contrary, the brain troubles which make themselves known in the optic nerve are mostly chronic lesions. If, therefore, one sees an intensely reddened optic nerve, it is essential that some other symptom be found before it can be assumed to betoken other trouble behind. This redness is seen much more often as the result of straining or irritation of the eye, or as a congenital defect in the eye, than as a disease of the remote tissues. An important change in the optic nerve, and which is often significant of brain disease, is swelling. We all know the relation which choked disc bears to cerebral tumor, and yet the optic nerve may have a perceptible degree of swelling, and its border be indistinct, and not indicate any cerebral lesion, but simply stand for an anomalous condition of the nerve itself.

Upon the edge of the optic nerve is not unfrequently seen a bright, white, opaque, striated surface, running out into the retina, which might be mistaken for an exudation. I remember when I committed that error. The appearance is by no means unfrequent, and is explained by the fact that the optic-nerve fibers have not lost their neurilemma as they pass over upon the retina. This is congenital, and makes little or no difference in the degree of vision. On the other hand, the optic nerve may be very pallid, and the vessels of the retina small, the nerve surface being slightly excavated. This pallor of the nerve and reduction in size of the vessels might be supposed to indicate atrophy; but it is simply indicative of the general poverty of the circulation and anæmia of the patient, and not due to any lesion of the nerve fibers.

There are many singular and anomalous conditions, which make their appearance in the optic nerve, which are familiar to the ophthalmic investigators.

I might here, perhaps, be permitted, without any breach of propriety, to quote a letter received last summer from an ophthalmic surgeon of Great Britain, which he wrote me in relation to a man whom he and I had treated, and from whom I was obliged to remove one eye because of a tumor. Before the tumor was fairly developed there was a detachment of the retina.

June, 1882.

Dr. H. D. NOYES.

DEAR SIR: Many thanks for your kind and instructive notes about the patient, P. When I first saw him, about a year ago, he had well-marked separation of the retina in the lower part of the fundus, which soon after extended over nearly the whole of the retina, leaving only a small chink at the inner aspect, giving a reflex with the ophthalmoscope; about six months ago the vision of the right eye became defective, accompanied with spectra and other objective symptoms of an anomalous character, followed by well-marked engorgement of the disc. Under treatment, the eye slowly recovered, leaving the optic nerve somewhat congested. During the whole time he was under observation there was no external inflammation, and no increase of tension in either eye. From the appearance of the right optic nerve, and the peculiar mental state of the patient, I supposed that there was some intracranial mischief, probably tumor of the brain.

Yours truly,

* * * *

* An abstract of remarks made before the Section in Practice, of the New York Academy of Medicine, January 16, 1883.

The point that I wish to bring out is this: That an experienced observer saw appearances in an eye which he regarded as an indication of inflammation, and, from other symptoms, he felt convinced there was intracranial trouble. The peculiar appearance of the patient's eye was fully explained by its refractive condition; he had a high degree of hypermetropia and astigmatism. After he had been furnished with suitable glasses, his vision became nearly normal, and he was able to go home, all of his strange mental symptoms having disappeared as soon as the difficulty of his vision was relieved. And this optical error had not been observed by the gentleman who had previously treated this man.

These are some of the objective errors of the eye, as, for convenience sake, I have designated them; but, putting these aside, there is a series of symptoms of a subjective character which are liable to be mistaken for trouble of the nervous system—such as spasm of accommodation and trouble of the external muscles of the eye, astigmatism, and hypermetropia. This has been dwelt upon by several observers, especially by Dr. Weir Mitchell, of Philadelphia. The cases of error in the refraction, so far as subjective symptoms are concerned, are essentially the same as those of spasm of accommodation without refractive anomaly. The class of cases which I am now signaling are those in which the patient makes but little complaint about trouble of the eye, and in some cases makes no complaint whatever. In the mind of the patient the emphatic symptom is something foreign to the sight, and he succeeds in impressing his idea upon the physician.

The first and chief symptom in these cases is headache, the headache being of any possible variety and of any possible degree—frontal, temporal, occipital, at the vertex, or it may be confined to one side of the head, although this is rare; this headache may or may not be on using the eyes; it may commence on waking in the morning, or be increased by mental labor. Sometimes connected with this headache will be another symptom, which seems still more significant, which is nausea. It is not uncommon for both to be associated together, and, while nausea is not constant, headache will be persistent. There may be giddiness, mental oppression, rarely palpitation of the heart, and numerous vague symptoms, according to the impressibility of the patient.

Suppose, now, that the physician thinks it his duty to look into the eye, to see if any inflammation may be there, and finding in one optic nerve congestion, and in the other congestion with opacity of its structure, he might be led to think that this was a case of chronic meningeal trouble, and that this was verified by the extreme hyperæmia found in the nerves; and that this conclusion was re-enforced by an appearance of exudation. Yet this condition is to be otherwise explained, and these appearances may be owing only to hypermetropia with eye-strain, and the headache, etc., be due to this strain. These same symptoms can make their appearance without there being a refractive error, and I shall take the liberty of quoting further letters, as they illustrate the way in which they present themselves:

Dr. H. D. NOYES.

NEW YORK, Dec. 10, 1882.

DEAR SIR: I should be very happy to have your opinion about the state of the eyes in this young lady's case. It seems to me that there is a slight spasm of the internal recti muscles (as the eyeballs do not roll out completely), which contributes toward the development of certain head symptoms. She complains of a permanent vague distress in the upper frontal region; a feeling of strangeness on seeing a mass of people together; sometimes of surprise on watching even a single person pursuing his ordinary avocations; dislike to look into a person's eyes; there is a loss of sleep, inability to fix the attention, sense of mental fatigue, frequent feeling of grotesqueness and strangeness, "as if she were not herself"—all indicating considerable disturbance of the psychic sphere, which I presume lies beyond the range of influence of the eyes, yet not, perhaps, altogether. There are hysterical convulsions; four years ago the patient had a transient guttite; later, a fall on the end of the spine, at which point there is now much tenderness on pressure, and has been much spontaneous pain. Nevertheless, present symptoms only date from the first of last September, after a month of continuous sea-bathing. Menstruation has been slightly delayed; there is no trace of uterine or ovarian trouble (examination has been made). Three possibilities present themselves to me: 1. Irritation of central nervous system from hyperæsthesia of Luschka's ganglion at coccyx, and spasm of internal recti as one symptom of such central irritation. 2. Exhaustion of nervous system from over-stimulus in sea-bathing—spasm of recti, thence cerebral symptoms. 3. Cerebral symptoms directly dependent on such exhaustion, and independent of ocular disturbance, which, so far as I can ascertain, is very slight.

Very truly yours, * * *

This evidently was a mixed case; but, upon critical examination, a large part of the apparent mental and cerebral disturbance with which this patient was afflicted was found to be due to intense spasm of accommodation; examination by the ophthalmoscope disclosed that there was an almost entire absence of refractive error, and that the myopia which seemed to be present was apparent and not real. Atropine has been freely and vigorously used up to the present time without wholly relaxing the spasm of accommodation, the origin of the spasm being remote, and may be due to an injury of the spine.

I have seen not a few cases where serious eye trouble has been dependent upon an affection of the spine, involving both the extrinsic muscles and spasm of accommodation. In another case, to which I beg to call attention, the principal trouble was not found in the error of refraction or spasm of accommodation, but in disordered muscular apparatus of the eye.

Dr. NOYES.

DEAR SIR: To-morrow will call upon you a Miss —, to consult you for a strabismus which I believe is congenital. Some years ago she saw Dr. —, who advised her to discontinue the matter, however, to me seems of some possible importance, for the following reasons: During her teens and until nearly twenty-five years of age (the patient is now thirty-two), she suffered extremely from violent headaches, and I am in question with me how far these may have been determined by the strabismus.

Three years ago she had, for the first time, an attack of melancholia—insanity—of a few weeks' duration, and another, lasting longer, last spring. The last attack followed immediately

upon a fall, in which she struck the back of her head violently. I saw her in this attack for the first time, and made a diagnosis of "primary curable dementia," directly induced by the concussion of brain, whose nutrition was impaired probably in various ways.

The girl is chloro-anæmic, with a very marked murmur in the carotid and at the base of the heart; and there is probably also lithæmia. Undoubtedly she must have had some individual predisposition to mental disease, but it does not seem to be hereditary. At present, she is merely in a condition of some mental debility ("psychische Schwäche") consecutive to the attack in the spring; but complains of many uneasy sensations in the head, indicating (I think) rather directly impaired nutrition than congestion. She has had hallucinations of hearing formerly, which seemed to originate in the roaring and buzzing in the ears, of which she now complains; and, similarly, she seems to be always on the brink of hallucinations of sight, which seem to originate in the difficulty, as she expresses it, of "bringing her eyes to a focus." What is especially important for the moment is, that she can not use her eyes without pain, and the enforced leisure is extremely hard for her mental health. This pain you may attribute to the strabismus, or also to the impaired nutrition of the base of the brain, for which I have now just begun to treat her. But I should very much like your opinion on this point. If you advise operation for the strabismus, they are quite ready for it. I have written at this length because it is desirable for you not to interrogate either mother or daughter as to the mental symptoms, about which they are both sensitive, and yet, of course, you should be acquainted with them.

Very truly yours,
* * * *

This case was one in which the symptoms were particularly emphasized, and were, in large measure, to be attributed to the condition of the eye. An operation for the strabismus was performed with very satisfactory results, both as regarded her health and the use of the eye.

This subject of the irritation which can be caused by the disturbances of the ocular muscles is one which has been debated considerably among eye surgeons. There is a variety of opinions, not in respect to the possibility of the disturbance of the nervous centers, through the debility of the ocular muscles, but upon the *degree* of influence which this condition exerts. But, while there are exaggerated assertions in respect to this matter, I am sure that the muscles of this eye, in the case just mentioned, exerted a far greater influence upon the health than is for the most part allowed to them.

As an illustration as to how the symptoms dependent upon strain of eye-muscles are expressed by a patient, I took pains the other morning to have a little girl, fourteen years of age, tell me, as completely as she could, the symptoms under which she suffered. She was brought to me by her mother, who said that the girl, for three years, had been complaining of severe headache, all treatment having been ineffectual. The mother was doubtful in her own mind whether to consult an expert on the eye, or one upon nervous diseases. She was, however, led to consult an oculist, by a friend who had been relieved of headache by the use of glasses. Symptoms in this child were as follows: When she looked hard at people, they seemed to go away from her; she has headache several days in the week, and will awake in the morning with it; she not only reads and

studies a good deal, but she keeps herself thus employed for the purpose, as she expressed it, "of forgetting the headache"; no tenderness over cervical vertebra; a jar or blow upon the head was unpleasant; faints easily from pain; to all appearances the child seemed to be healthy; there was slight tenderness over the supra-orbital nerve on the right side; in church the minister seems to go away from her; occasionally there has been nausea.

I tested her with the usual tests for difficulties of the ocular muscles, and the usual phenomena which we rely upon by prisms failed to indicate any important muscular error; but, when the child was asked to look at the finger held close to the face, it was difficult for her to keep both eyes upon the object, and, if one eye was covered, the other eye would deviate several lines. Diagnosis in her case was: extreme debility of the internal recti muscles, which, with accompanying spasm of accommodation, had given rise to the persistent headache.

The symptoms which persons give are not only of nausea, headache, and inability to look fixedly at objects, but of dizziness and mental oppression. In young subjects the accommodation is so great that their attention is not attracted to any connection which may subsist between the headache and the eye. Such, in brief, is a statement of this class of cases.

Now, how are the cases to be recognized, and how are these errors to be avoided?

In the first place, objective errors, which may be recognized by the use of the ophthalmoscope, require a sufficiently large experience in its use in order that the surgeon may fully appreciate both normal and abnormal conditions; but more important than this is that the instrument should not be employed in one method only—that is to say, by the indirect method, where the lens is held in one hand and the instrument in the other; that method is incapable of giving adequate information; it gives you a view of the bottom of the eye, but not of the refractive state of the eye; therefore, the best method is by what is called the direct method, or upright image, in which the instrument has to be supplied with glasses to correct the optical errors of the patient, and by which you can tell whether its condition is normal or abnormal, as far as refraction goes. Then, in addition to this, there must be an examination of the quality of sight, by proper test types, aided and carried to completeness by a spectacle box; and, finally, under suitable circumstances, resort to the use of atropine.

If you are to examine a patient who may develop some notable disease of the brain, and who may in consequence ultimately lose his sight, the use of atropine should be avoided, as the application of the atropine would be very liable to be remembered by that individual, and he might attribute his loss of sight to its use. Therefore, if you do propose to use atropine, and there is any reason to suspect brain trouble, it is proper to notify the patient that no ultimate detrimental result will follow its use. It, however, is not necessary in the large proportion of cases to use atropine in your examination where there is reason to believe that there is brain trouble. On the other hand, taking the cases where the symptoms are of a functional or subjective kind—nausea,

headache, and such symptoms as have been described, and there are no other well defined evidences of brain lesion—then atropine may both relieve the symptoms as well as clear up the diagnosis; it does frequently remove the headache, although it is only temporarily; afterward, the refractive errors are to be corrected by suitable glasses. The degree to which these subjective symptoms make their appearance varies according to the temperament of the person and their natural susceptibility. It will be found that those persons suffering from exhaustive conditions of a chronic character are more susceptible; especially is this the case with those suffering from uterine disease.

If it be a muscular error, the treatment consists in rest and the suitable employment of prismatic glasses, with proper attention to any of the remote discoverable lesions which may have an influence in producing this trouble. Sometimes these muscular and refractive errors are combined, so much so as to make the prescribing of suitable glasses extremely difficult.

[In reply to various remarks made in the discussion, Dr. Noyes spoke as follows:]

MR. CHAIRMAN: In my reading I omitted two or three things, for fear of saying too much. Now, in reply to the different remarks upon the same, I would say that, in reference to the pathology of cases of muscular trouble, we have to remember that the nerves which are at fault are the third, fourth, and sixth, all of which cluster, in their origin, at the medulla oblongata. This central spot makes them easily the agents of transmission for causes which may proceed either from the cerebrum or cerebellum, or from the spinal cord.

The cases which I have cited are of a very marked type, chosen purposely to exhibit their most decided features. Many others exhibit fewer and less impressive symptoms; and, of course, with many persons the complaint has respect only to functions of the eye. These last would naturally not cause any mistake in diagnosis. As to the curability of the cases under consideration, I may put the matter as follows: I might present a very large list of persons who have been perfectly relieved of all their symptoms, both local and general, by the adjustment of glasses of various kinds adapted to both refractive and muscular faults, or by the performance of operations on the ocular muscles—and I mean this statement to apply to those in whom the general symptoms have been predominant, i. e., headache, etc. Another category will include persons who have derived a considerable degree of relief from ocular treatment, but who have not been entirely cured. This will embrace very many persons who are either in reduced general health, or have some chronic ailment, or are of a neurotic temperament. To such persons the benefit afforded is often very important, inasmuch as the function of sight and enjoyment of vision have such controlling importance over everybody's happiness. In them correct and judicious eye treatment means much, although it can not pretend to cover the entire case. Necessarily, the degree of value in the eye treatment will be variable. There are other cases in which general symptoms take precedence above eye symptoms, and the attempt to do good by relieving the latter, will be futile. Or the true

mode of relieving the eye troubles will be to improve the general health, to abate or control a neurotic tendency, to get rid of chronic diseases, to lighten the burdens and sorrows of life, etc. It is needless to dilate in this direction. My aim has been to call attention to a class of cases in which the local difficulties simulate and suggest other lesions, but are in themselves the essential part of the disturbance.

NOTE ON THE USE OF

CONVALLARIA MAIALIS.

By BEVERLEY ROBINSON, M. D.,

PROFESSOR OF CLINICAL MEDICINE IN THE DEBBENHOF HOSPITAL MEDICAL COLLEGE.

DURING the past three months I have made use of the fluid extract of convallaria maialis in quite a number of cases of chronic cardiac disease. In it I recognize a new cardiac tonic of considerable value. It should be approximated in its therapeutic effects with those of caffeine and digitalis. Not that it resembles closely in all its properties these well-known drugs, but because it is analogous to them in having an appreciable stimulating effect upon cardiac power. When the fluid extract of the root of convallaria has been given in suitable doses (five to ten drops every two or three hours) to patients in whom cardiac incompetency is already apparent, in view of the rational symptoms of dyspnea, oppression, localized pain over the præcordia, and palpitations, it will aid in diminishing these phenomena in a notable degree. When we have, in addition to these functional symptoms, the ordinary physical signs of cardiac disorder, such as weak, rapid, and irregular pulse; tumultuous, unequal heart-beats, with a blowing murmur at one or other orifice; œdema of the lower extremities, with more or less serous effusion into the large cavities of the body—we shall also be able to remark a certain amount of benefit arising from its use. Thus, the pulse becomes stronger and more regular, the heart-sounds acquire additional force, and the painful palpitations disappear. Dyspnea is often favorably modified, and the respiration becomes slower and deeper. Anasarca is not usually much influenced by the exhibition of this drug, and the urine is scarcely if at all increased in quantity, nor are its solid constituents manifestly modified in their eliminated quantities. Usually the stomach accommodates itself well to the use of this drug, and in those cases where I have observed intolerance following its exhibition I have attributed the nausea, or rejection, to beginning uræmic condition.

While I believe that this drug has some power in controlling cardiac action, I am of opinion that this is exercised mainly through the pneumogastric nerves, and not upon the muscular fibers directly in any considerable degree. This view appears to me to be confirmed by its striking effects in diminishing the intense dyspnea of asthma, and in quieting palpitations in a heart-failure patient. I have not found that convallaria restored rhythmic action to the crippled heart in a degree sufficient to make it a direct rival a local substitute of digitalis, nor has it convinced me that it is the peer of digitalis in adding to cardiac contractility. Over

digitalis, however, it has apparently *one* very great advantage—viz., it does not in man, at least, and in the doses mentioned above, take on cumulative effects or produce any poisonous symptoms, which have been feared on account of its well-known pernicious action, even in relatively small doses, upon the lower animals. As compared with the use of caffeine, I would say that it is greatly the inferior of this latter drug when we desire to obtain considerable diuretic effects. As to the comparative power of these two drugs in their action upon the heart, it is as yet impossible to assign their precise place. Still, I am disposed to think that convallaria is somewhat more of an invigorator of cardiac power than caffeine is. At all events, in man its action is a less variable quantity, for while caffeine, in even small doses of two or three grains, will occasionally produce congestive phenomena of distressing character, and, again, in similar or much larger doses, will prove inert, convallaria appears to produce about similar effects in persons of different temperament. Thus far, in my own experience, convallaria has been more readily accepted by a sensitive stomach than either caffeine or digitalis.

A CASE OF FREUND'S OPERATION.

By J. E. JANVRIN, M. D.

THE following case was operated upon on June 8, 1881:

The patient, a lady of fifty years, a widow, and the mother of several children, came under my care in April of the same year, and, on examination, was found to be suffering from carcinoma of the cervix and body of the uterus.

Her history for the year preceding had been that of one suffering from this disease—severe pain, hæmorrhages, and gradual wasting. During the early part of April I curetted the uterus, removing the tissues as thoroughly as possible by this operation, and for a period of six weeks she was much relieved.

Soon the symptoms of a return and extension of the disease manifested themselves, and, at the urgent solicitation of the patient, after all the dangers of the operation had been fully set forth to her, it was decided to remove the entire uterus.

As far as could be ascertained by a thorough examination, the disease had not progressed beyond the uterus. This view was concurred in by Dr. E. Noeggerath, who saw the patient in consultation with me, as was also the propriety of resorting to the removal of the entire organ.

The operation was performed on the 8th of June. Listerism in all its details was fully carried out. Drs. Noeggerath, T. A. Emmet, E. H. Peaslee, Herrick, Currier, and J. E. Allen were present, and rendered most valuable assistance.

On opening the abdominal cavity, and exploring it carefully, it was found that the disease had extended anteriorly, involving the cellular tissue between the uterus and bladder. There was also some evidence of disease in Douglas's cul-de-sac. The operation was proceeded with, however, and the ligatures passed according to Freund's method, three upon either side. In this case those upon the left side first,

then upon the right. After cutting through the peritonæum between the bladder and the uterus, and while endeavoring to separate with my finger the bladder from the cervix, although the greatest care was used, yet, on account of the extreme friability of the tissues, a small rent was made into the bladder. It then became evident that the disease had involved the posterior wall of the bladder. On account of this extreme friability of the tissues, it was found impossible to remove the cervix with the body of the uterus. The body itself was rapidly enucleated. Two fine carbolized silk sutures completely closed the rent in the bladder, the final ligature on either broad ligament having been applied just before enucleating the uterus. The abdominal cavity was carefully sponged out and the incision closed by silver sutures.

The patient, almost pulseless, was removed to her bed, wrapped in warm blankets, and hot bottles applied to the extremities. Hypodermics of brandy had been given frequently during the latter part of the operation, and were continued at short intervals for six hours after the operation was completed. Hæmorrhage to the amount of six ounces occurred during the operation. Operation lasted an hour and a half, being completed at 4.30 P. M. By midnight, the effects of the ether having worn off, she was quite conscious, and began to take milk and brandy by the mouth, which was continued every hour, one ounce of the former and half an ounce of the latter.

June 9th.—3 A. M., pulse 140, and extremely feeble, respiration 30, temperature 100°. Reaction apparently just beginning. 5 A. M., has been sleeping at short intervals (ten or fifteen minutes) during greater part of the night. Catheter passed, and an ounce or more of bloody urine drawn. 10 A. M., some pain and considerable restlessness. Hypodermic, Magend. sol. m viij. Temperature 100°, respiration 28, pulse 120 and slightly improved. Catheter, two ounces urine somewhat tinged with blood. 2 P. M., the brandy and milk, in the proportions previously mentioned, has been continued every hour; also an ounce of milk on the half hour between. 9 P. M., temperature 102°, pulse 140, respiration 30. Has just vomited freely. Brandy, 3 ij, hypodermically, followed in half an hour by an enema of ten grains of quinine, with half a tablespoonful of Valentine's beef juice, and an ounce of brandy. 10.30 P. M., the enema of quinine, beef juice, and brandy repeated. Patient perfectly conscious, but failing rapidly. In fact, reaction has never fully set in, and she is sinking from shock.

Death took place at 11.30, patient being conscious and able to converse a few minutes before its occurrence.

Post-mortem showed no evidences of peritonitis. The cavity of abdomen was free from bloody serum, and perfectly clean. There had been no leakage of urine through the small rent in the wall of the bladder, the sutures having held the edges in perfect apposition.

Remarks.—In reporting this case of unsuccessful attempted relief from the painful and certain death from the disease itself, I will simply state that, from my experience in this case, and from observation of others—some of which have been operated upon by Freund's method, and some *per vaginam*—I have no hesitation in saying that of

the two operations the latter is by far the easier of performance, and holds out the best chance of recovery.

In this case, the uterus and all the diseased parts surrounding it could not have been removed by either method.

The extension of the disease to the posterior wall of the bladder and its infiltration into Douglas's cul-de-sac could not be made out prior to the operation. There had been no symptoms pointing to bladder trouble of any kind. Neither, on examination, could the slight thickening in the cul-de-sac be distinguished.

This being the case, as far as we could discover, it was thought best at the time to attempt Freund's method of operating. The unforeseen complications prolonged the operation, and contributed largely to the unfortunate termination of the case.

NEW YORK, SATURDAY, FEBRUARY 10, 1883.

THE NEW CODE STANDS.

ON Tuesday last, the first day of the seventy-seventh annual meeting of the Medical Society of the State of New York, Dr. Edward R. Squibb, of Brooklyn, introduced before the meeting certain resolutions having for their purpose the abrogation of the code of ethics adopted at the meeting of 1882, and the re-establishment of the code previously in force—namely, the code of the American Medical Association. The full text of these resolutions will be found in our formal report of the proceedings. They were made the special order of business for the evening session. At that session, after three hours of discussion in committee of the whole, a vote was taken, the ayes and nays being called, with the following result: Ayes, ninety-nine; nays, one hundred and five. It was ruled that the resolutions, being of the nature of an amendment to the by-laws, required a two-thirds vote in the affirmative for their adoption; it will be seen that they did not secure even a majority.

In view of the fact that many of the county societies had instructed their delegates to vote for the restoration of the old code, we presume that most of our readers would not have been surprised if Dr. Squibb's resolutions had been carried. There can be little doubt, however, that the recent decided expression of opinion by the Medical Society of the County of New York in favor of the new code, although declining to instruct its delegates, went far, by its moral effect, to incline a number of permanent members and uninstructed delegates to oppose the restoration of the old code. That expression of opinion on the part of our county society was embodied in a vote taken at a special meeting held on the 29th of January, the meeting having been called for the express purpose of considering the question of the code. The vote stood: one hundred and forty-seven in favor of sustaining the new code, and sixty against it. The moral effect of this formal action of the county society does not appear to have been offset by a petition, signed by many prominent New York physicians, setting forth their belief that the new code was not acceptable to the majority of the profession—which petition figured in the debate in the committee of the whole at the meeting of the State society.

After the vote was announced, Dr. Roosa, in fulfillment of the intention expressed by him at the meeting of last year, introduced his resolution, the gist of which is contained in the declaration that "the only ethical offenses for which they [the medical profession of the State of New York] claim and promise to exercise the right of discipline are those comprehended under the commission of acts unworthy a physician and a gentleman." Action on this resolution was promptly postponed until next year.

Thus, then, the vexatious question of the codes may be looked upon as settled, at least for the time being. This in itself is a matter for congratulation, and it is still more gratifying to be able to record the fact that, during the discussion, no offensive tactics were resorted to on either side, nor did the warmth of debate lead to any remarks of a rancorous nature. Indeed, while each side fought hard for its cause, the meeting was notably good-natured in its tone. We sincerely trust that the action taken may prove to be wise, and that its effect may not in the long run act as a bar to the affiliation of our State society with those bodies that formerly worked in harmony with it.

THE NEW PHARMACOPEIA.

IV.

In former articles we have mentioned some points in the pharmacy of the pharmacopœia, but only incidentally. It is our present purpose to speak more fully of this feature of the work. We are struck at the outset with some judicious directions as to the fineness of powders. Powders are termed "very fine," "fine," "moderately fine," "moderately coarse," and "coarse," or, as expressed numerically, "No. 80," "No. 60," "No. 50," "No. 40," and "No. 20," according as they will pass through a sieve of eighty (or more), sixty, fifty, forty, or twenty meshes to the linear inch. In certain instances, intermediate degrees of fineness are directed, designated by numbers indicating the number of meshes to the linear inch of the sieves through which they should pass. The establishment of these standards substitutes exactness for fancy, and, so far as we can see, is not likely to prove burdensome to the pharmacist.

We infer that tinctures of fresh herbs have found some favor with the committee, for we notice a general formula, under the title "*tinctura herbarum recentium*," which directs fifty parts of the fresh herb, bruised or crushed, to be macerated for fourteen days with one hundred parts of alcohol, the liquid to be then expressed and filtered. The reader may infer either that the committee entertain the idea, although regarding it as still *sub judice*, that it would be an advantage to use all herbs in their fresh state so far as practicable; or else that they consider it well that only some particular plants should be employed fresh in the preparation of tinctures. If the latter is the case, it is to be regretted, we think, that the committee have not specified those individual plants. Moreover, seeing that they evidently had under consideration the elements that conduce to the efficiency and uniformity of vegetable drugs, it is strange that they have not in a greater number of instances directed from what country the plant should be obtained, and at what period of its growth or at what time of the year it should be gathered—factors that are well known to be of paramount importance in determining the activity or the worthlessness of the drug in many cases.

Triturations seem to have commended themselves somewhat more decidedly to the committee, for they have not only given a general formula for their preparation, but actually made one trituration official—that of elaterin. There are those who

attribute to exceedingly fine comminution the effect of heightening the activity of certain drugs, and we may look to see a somewhat extensive use of various triturations by those gentlemen. We are inclined to think, however, that the profession in general will stand aloof from these preparations except in the case of drugs of which, like elaterin, the dose is so small that, if it is to be given in the form of powder, convenience calls for an increase in its bulk. Powders are not very elegant preparations at best, and it does not seem to us that their multiplication is at all desirable. In regard to sugar of milk, we have already mentioned its employment in the new class of preparations termed abstracts, and we may add that it now takes the place of sulphate of potassium in Dover's powder. A liquid counterpart of Dover's powder is found in the new tincture of ipecac and opium, made of deodorized tincture of opium, fluid extract of ipecac, and alcohol.

Simplicity would have been consulted, we think, if the diluted acids and other like preparations had been dismissed from the list. Their presence cumber the book, and pharmacists will be expected to keep them on hand, we presume—all for no good reason that we can see. Their uselessness is exemplified in the second formula for liquor ammonii acetatis (p. 194), in which, instead of adding carbonate of ammonium to diluted acetic acid, we are directed to employ certain specified quantities of carbonate of ammonium, acetic acid, and water.

In several of the liniments, cotton-seed oil is substituted for olive-oil—a very commendable change, we think, since the former oil is less expensive and equally good for the purpose. Cotton is directed to be used in certain processes of percolation, especially in making several of the aqueous preparations of the essential oils. For instance, to make anise water, we are told to add two parts of oil of anise to four parts of cotton, "in small portions at a time, distributing it thoroughly by picking the cotton apart after each addition; then pack it firmly in a conical percolator, and gradually pour on distilled water until one thousand parts of percolate are obtained." We have heard the objection made to this use of cotton, that in the repeated acts of picking it apart some of the oil will necessarily stick to the fingers, so that the amount left to enter into the finished product will be indefinite.

While on this matter of percolation, we can not forbear to enter our protest against the burdensome and wholly needless work entailed upon the pharmacist by the fact that the pharmacopœia adheres persistently to weights instead of measures of capacity. It is idle to pretend that, for ordinary purposes, the one is any more exact than the other. We think, too, that the use of specified quantities, by weight in the case of solids, and by measure in the case of liquids, would have answered the purpose quite as well as the vexatious proportional parts given in the pharmacopœia. The use of the metric system of weights and measures, too, whatever may be said in its favor from a theoretical point of view—and thus far we have noticed nothing convincing—has failed to find favor with our countrymen, and we doubt the wisdom of attempting to force it upon them officially.

In the formula for aromatic spirit of ammonia we notice the injunction to use "alcohol, recently distilled, and which has been kept in glass vessels." If there is any real necessity for such nicety as this direction calls for, we think the formula has no more title to be given in the pharmacopœia than those for making the alkaloids, or than several others that are omitted as coming within the special province of the manufacturing chemist, for it seems either that the pharmacist will have to make his own alcohol, or else that he will have to adopt extraordinary devices to satisfy himself that the alcohol he buys for this purpose is recently distilled and has been kept in glass vessels.

In the preparation of aromatic sulphuric acid, the new pharmacopœia directs the use of tincture of ginger and oil of cinnamon, instead of ginger and cinnamon in powder. This may result in some diminution of astringency, but we are inclined to think that the acid is so decidedly the essential constituent of the preparation that it may be prescribed in its new form with confidence that its action will be found not to have been materially modified.

An error seems to have been committed in making the *leaves* the official portion of the *Hamamelis virginica*, instead of the young twigs. We will here observe, too, what should have been mentioned in a former article, that, in making only one species of viburnum official, the framers of the pharmacopœia would probably have done well to choose the *Viburnum opulus* instead of the *V. prunifolium*.

We come now to a matter of very great importance, namely, the preparations of opium. The opium of the old pharmacopœia, according to the new pharmacopœia, contained about 8 per cent. of morphine, whereas that of the new pharmacopœia contains 9 per cent., or more; the powdered opium of the former contained 10 per cent. or more of the alkaloid, while that of the latter contains from 12 to 16 per cent. The laudanum of 1870 contained 9 per cent. of the powdered opium of 1870 (i. e., 0.9 per cent. or more of morphine); the laudanum of 1880 contains 10 per cent. of the powdered opium of 1880 (i. e., from 1.2 to 1.6 per cent. of morphine). With all these variations, it may happen that a specimen of the laudanum of the new pharmacopœia shall have a morphine strength, in comparison with that of the old preparation, of sixteen to nine—in other words, it may be very nearly twice as strong! Is not this a good deal to pay for the whistle represented by the desire to have all tinctures made with a uniform proportion of the crude drug? Uniformity is desirable, no doubt, and in itself the increased strength of the laudanum of 1880 is not in the least objectionable. We fear, however, that serious mistakes will be made in practice unless the most stringent precautions are taken.

At the outset, we advised our readers to make themselves acquainted with the new pharmacopœia. It is unsafe to remain in ignorance of its contents. It was prescribed that the opium, with no other thought than the same prescription has occasioned him for years past, and that the prescription is taken to an apothecary who thinks it incumbent on him to follow authority *ruat cælum*; and the consequences, especially

if the patient should happen to be an infant, may be fatal. We therefore advise all physicians to specify on their prescriptions whether they mean the laudanum of 1870 or that of 1880, and we would urge upon all apothecaries never to dispense the latter unless it is specifically ordered. Even these precautions, we fear, will scarcely suffice as a protection against misunderstanding in the matter of the familiar mixtures containing laudanum—Dewees's carminative, for instance.

It remains only to speak of a few matters pertaining to style and accuracy, in regard to which features the book is singularly meritorious. Very properly, as it seems to us, the committee use the word gramme instead of grain, and we are unable to see why they should use liter instead of litre. They say, also, "deodorized tincture of opium," but "denarcotised opium." The *mistura rhei et sodæ* contains no soda, but a salt of sodium. It seems to us that the expression *extractum sarsaparillæ fluidum compositum* would be better than *extractum sarsaparillæ compositum fluidum*; a fair inference from the latter would be, that there was another compound extract of sarsaparilla that was a solid, which is not the case.

Dried alum is said to answer to "the same reactions" as alum—meaning, doubtless, the same *tests*. In two of the chemical formulæ, that of acetic ether (p. 25) and that of hydrochlorate of apomorphine (p. 40), we note an absence of the punctuation necessary to separate the formula of the acid from that of the base.

The style of writing is generally clear and in keeping with the idioms of the English language. In several places, however we have noticed the abominable expression "the above," meaning the foregoing, also occasional slips in punctuation. The book is remarkably free from printers' errors, only one of which occurs to us now—that of "*Apocynum cannabinum*" for *Apocynum cannabinum* (p. 447).

On the whole, the new pharmacopœia seems to us a most creditable production, and the profession will no doubt recognize the debt of gratitude they owe to the committee for their patient and arduous labors in preparing it. At the same time, we have not scrupled to point out what seemed to us its weak points. The more familiar physicians become with the work, and the more it is discussed, the better fitted will the next committee be to produce its superior in the pharmacopœia of 1890.

THE NEW YORK WATER FAMINE.

Now that the Brooklyn Bridge is approaching its completion, it becomes evident that we must provide some other place for our "bosses." This statement needs no argument to support it, for even inanimate objects show their appreciation of the fact. No sooner does a commission meet to consider the necessity of building a new aqueduct than the old aqueduct, loyal witness that it is, at once begins to dole out its supply of water even more stingily than before. For many months past we have been accustomed, whenever water was to be had at all above the ground floor, to a dribble in comparison with which the drippings from an umbrella might be called a

torrent; but on a recent occasion the aqueduct fairly outdid itself. On the night of the 24th of January taps that before had shown no particular falling off from their accustomed oozing would yield not a drop of water. This action on their part came in the very nick of time, for the engineer of the Croton Aqueduct Department had just testified that the aqueduct was running at its full capacity. No testimony could better have served the purposes of the rapacious "bosses" than just this combination of Mr. Newton's statement and such a signal failure of the aqueduct. If the aqueduct, running at its full capacity, utterly failed nevertheless to send a drop of water twenty feet above the sidewalk at dead of night—and that, too, without any unusual demand having been made on it by the Fire Department or in any other way known to the public—how could there be any question but that such an aqueduct was manifestly inadequate?

We are bound to suppose that the aqueduct kept on running at its full capacity, but that in some mysterious way that capacity was suddenly reduced, possibly by means of a vaso-constrictor effort on the part of the conduit itself, exerted for the purpose of impressing the commission. Unfortunately for the ring, however, the aqueduct proved unequal to a very prolonged course of deception, and ever since the date which we have mentioned there has been a better supply of water than for several weeks before. It is not a little singular that this spasm of the aqueduct should have relaxed on the very day that the newspapers gave publicity to the leading points in a document presented to the Water Commission by a committee of the Tax-payers' Central Committee, in which we note the following significant passage: "The water leaves the Croton Aqueduct at One Hundred and Thirty-fourth Street, and is conveyed through six iron mains to Ninety-second Street, where it enters the aqueduct again. Between One Hundred and Thirty-fourth and Ninety-second Streets there is only one outlet, a twenty-inch main, supplying West Harlem, East Harlem being supplied from the reservoir. It frequently happens that the depth of water in the aqueduct at High Bridge is six feet two inches, while in the aqueduct at Ninety-second Street it is only three feet or less, the velocity of the water at both points being the same. This would mean a loss of two thirds of the volume of water passing out of the aqueduct at One Hundred and Thirty-fourth Street. This was denied by the Commissioner of Public Works in 1879, on the authority of his subordinates, but not of his own personal knowledge. To explain what became of the water between One Hundred and Thirty-fourth Street and Ninety-second Street, the committee said that there were at One Hundred and Nineteenth Street, the lowest point, twelve twelve-inch holes, known as 'blow-offs,' which, when opened, discharged the water into the sewers. There were similar openings at Manhattan Street, between One Hundred and Twenty-sixth and One Hundred and Twenty-seventh Streets. It was not charged that these openings were unlawfully or improperly used, but they clearly revealed a way by which the facts mentioned could be accounted for."

Bearing in mind that the engineer did not state how far in

its course the aqueduct was running at its full capacity, the New York tax-payer may admit the possibility that these "blow-offs" were not "unlawfully or improperly used," and look upon the aqueduct as an untrustworthy witness; but it would not be well to call upon him in support of that view.

THE TREATMENT OF FISTULA IN ANO.

At a recent meeting of the Société de Chirurgie, of Paris ("Union Médicale," Oct. 10, 17, 1882), there was a very interesting and exhaustive discussion upon the treatment of fistula, which called out the views of some very well-known surgeons. It was begun by M. Lucas-Championnière, who read a report on a recent memoir by Dr. Queirol, of Marseilles, upon the use of the elastic ligature. The memoir was based upon five cases, which seemed to constitute a strong argument in favor of this method of treatment, and to justify the conclusions that the method was free from danger even when the fistula extended high up; that it gave rise to few complications, while the operation with the knife was not infrequently followed by purulent infection, phlegmon, and relapse; that it avoided hæmorrhage; that it provoked no inflammatory reaction, or inflammation in the vicinity; that it was followed by no relapse; that the wound healed from the bottom; that the patients were able to continue their occupations from the day of the operation; and that the procedure caused so little pain that chloroform could generally be dispensed with. Again, that a general bad condition did not contraindicate the operation. M. Lucas-Championnière had himself practiced this operation a certain number of times. In some cases it was painless, in others there was more or less pain, and once the pain had been very severe. It had seemed to him that this symptom was in relation to the size of the ligature used, and that the larger the elastic the greater the suffering. He used a very small ligature, and Queirol had shown, with Simon, that for the success of the operation it was not necessary to draw the cord very tight, but that a moderate constriction served to divide the tissues. The cord cut the tissues, and cicatrization proceeded behind it. He had observed, in opposition to Queirol, that, if the patients were allowed to go about immediately after the operation, there would be more or less severe pain, and he advised that they be confined to bed for the first few days.

M. Verneuil formally protested against the adoption of this procedure. Without doubt the elastic ligature had its use in cases of small, superficial fistulæ without diverticula or undermining of the skin; but in other cases it should be rejected, and even in them it had no advantages over the use of Paquelin's cautery—a method so simple, so easy, and so efficacious. He also sided entirely with those who rejected the bistoury for this operation. In fact, the bistoury was a cause of complications, of hæmorrhage, of erysipelas, and of other accidents more or less grave. He also rejected the éraseur, the use of which exposed the patients to the same accidents as the bistoury. He had lost one patient at the Hôtel Dieu, from hæmorrhage, after operating with the éraseur. He greatly preferred the cautery, which was applicable to all fistulæ, great or small, never caused hæmorrhage, and prevented relapse infinitely better than the elastic ligature. In fact, a return was generally the result of an incomplete operation, and the ligature always left something incomplete unless as many cords were used as there were diverticula, in which case the operation was greatly complicated.

As to pain, it had always been very severe when he had used the ligature. His patients had all complained of great suffering, and one poor woman, affected with tuberculosis, had died five or six days after the operation, worn out with the suffering and

lack of sleep. It was alleged in favor of the ligature that it dispensed with the use of the tent for stuffing the incision, but for his part he had abandoned the detestable use of the tent twenty-five years ago. Again, the cautery was much to be preferred to the elastic ligature in cases of albuminuria, gout, gravel, or any other diathesis. He denied to the ligature any advantages over the modern operations; but, on the contrary, he found in it the gravest inconveniences, especially when dealing with fistulæ with numerous diverticula, or in hard and resistant tissues. The method could in no way compare with the use of the cautery for simplicity, effectiveness, or avoidance of pain. In all cases he advised that the patient be not allowed to go about too soon.

M. Marc Sée remarked that a relapse was generally the result of an incomplete operation, and that the objection to the ligature was the difficulty with which it could be made to cover the entire field of the disease. He had, moreover, found, in opposition to Queirol, that it was necessary to make the constriction as tight as possible, and that the cord should be stretched to five or six times its natural length. With this amount of stretching the pain only lasted for an instant, and the tissues were divided much more quickly. The ligature caused no hæmorrhage, but, according to his experience, both the cautery and the éraseur sometimes did.

M. Desprès wished to say a word in favor of the éraseur and the bistoury. According to him, neither the cautery nor the elastic ligature accomplished what was promised for them, particularly in the way of avoiding hæmorrhage. The cautery produced deep and extensive burns, and caused great pain. He preferred the éraseur, which accomplished in a few moments, with the aid of chlorotorm, all that was possible. In superficial fistulæ the bistoury was all that was necessary. He had operated with the bistoury in 220 out of 230 or 240 cases, and had never had hæmorrhage or lost a single patient from purulent infection at the Cochin hospital, but he never operated off-hand, and always prepared his patients by a week or two of treatment with repose, cataplasms, lotions, and baths. Besides these 220 operations with the bistoury, he had used the éraseur ten or twelve times in cases of deep fistulæ, and never had seen a relapse.

M. Terrier thought that, considering the multiplicity of the causes of fistula, it would be strange if any one operation were best adapted to them all. He spoke at some length upon the different pathological conditions, and the various means at the disposal of the surgeon for dealing with them.

M. Desprès attached little importance to the presence of diverticula unless they were near the skin, when they should always be divided. When they were deep and near the rectal opening, all that was necessary for their cure was the division of the tract which connected the cutaneous with the rectal orifice.

M. Berger thought Desprès the most favored of surgeons in having cured 230 or 240 fistulæ without concerning himself with diverticula. For his part, they always returned when the operation was incomplete and the diverticula were not laid open. There was one class in which operations were often unsuccessful—that in which the cutaneous openings were situated in hard, infiltrated, brawny skin, resembling the condition of elephantiasis. In such cases it was necessary to remove this tissue completely to secure a good result. In some cases, in spite of dressings and the most minute precautions, healing could not be induced. Often in these cases the lack of success was due to a bad general state of the patient, who was more or less under the influence of the tubercular diathesis. He had seen a fistula which had resisted every kind of local treatment cured in a month by the administration of cod-liver oil.

M. Trélat said that when fistulæ were seen the tracts of which presented conditions unfavorable to cicatrization (callosities, fungosities, etc.), it was necessary first to destroy the fungous tissue, and bring back the tracts into a condition to heal. On this point he agreed entirely with MM. Terrier and Berger.

M. Duplay thought, also, that it was impossible to lay down any general rule for the treatment of an affection which showed such marked differences. All fistulæ, he thought, could be reduced to two general varieties—the simple and the complicated. For the latter it might be necessary to resort to multiple incisions, to alternative applications to the walls and bottoms of the tracts, to very careful dressings, etc. For the simple ones, which did not mount far above the sphincter, the kind of operation was of little importance. Such a fistula might be divided with a bistoury, with scissors, with Paquin's cautery, with the galvanic cautery, or with the elastic ligature. This last procedure, which was particularly under discussion, had incontestable advantages over the others (admitting that it really had all the merits claimed for it) in its extreme simplicity, which rendered it hardly worthy of the name of an operation; and it constituted a real progress in the treatment of the disease.

M. Desprès believed that he ought to protest, in the name of progress, against the proposition enunciated by MM. Trélat, Berger, and Terrier, that the important element in the treatment of fistulæ was medication of the tract. According to his idea, a fistula was cured when the internal orifice was united with the external by section, so that gas and fæces no longer passed by an artificial route.

NEW YORK IN MEDICAL LITERATURE.

DURING the first half of this century New York was often spoken of contemptuously by the profession throughout the country, the reproach being cast upon the physicians of the city that their energies were wholly given up to money-making, that they seldom made any noteworthy additions to medical literature, and that contemporary medicine was little if at all the gainer by their existence. It can not be denied that these taunts were deserved. But a notable change has taken place within the last thirty years—indeed, even within the last decade. Men who are now active writers and society workers were accustomed to say, a few years ago, and with rather an air of satisfaction, that they were “no writers.” This change was graphically set forth in the President's address to the Academy of Medicine last week—an address of which we shall endeavor to lay an abstract before our readers very soon.

It seems that Dr. Barker has taken pains to ascertain the varying literary activity of the New York profession as indicated by the number of books that have emanated from them during the present century. He finds that from the beginning of the century to the year 1850 one hundred and nine such books were published, while in the thirty years, from 1850 to 1880, there were two hundred and thirty-six. We understand that these figures refer only to original works, leaving translations, revisions, and the like, out of account, and excluding also all contributions to periodicals. The contrast is certainly striking, and, although the gauge is quantitative only, we do not hesitate to assert that a very large proportion of the leading American medical text-books are of New York origin, and that that proportion is steadily increasing.

THE NEW YORK ACADEMY OF MEDICINE.

FOLLOWING Dr. Barker's inaugural address, at a meeting of the Academy held on the 1st inst., complimentary remarks were offered by Dr. Detmold, Dr. Post, Mr. F. Seymour Haden, of

London, and the Vice-President, Dr. Weir; after which, the Vice-President being in the chair, the following resolutions, offered by Dr. W. M. Carpenter, were seconded and unanimously adopted:

Whereas, To those of us who have been accustomed to attend the meetings of this organization, the concise and comprehensive *résumé* of the history and present condition of the New York Academy of Medicine to which we have listened has passed before us like a pleasing and edifying panorama:

Be it Resolved, That we hereby express our hearty appreciation of the fidelity and untiring industry of our President for the welfare of this institution.

Resolved, That we are ever ready to respond to his call, and indulge the hope that what we have received from our most worthy founders, whether it be physical or scientific, constructed of brick and stone, we shall be able to transmit constructed of solid marble.

The Academy then adjourned to partake of the loving cup.

Proceedings of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

THE seventy-seventh annual meeting was held at Albany on Tuesday, Wednesday, and Thursday, February 6, 7, and 8, 1883, the President, Dr. HARVEY JEWETT, of Canandaigua, Ontario County, in the chair.

FIRST DAY.—TUESDAY, FEBRUARY 6TH.

Morning Session.

Prayer was offered by the Rev. Albert Foster, of the Tabernacle Church.

The President then proceeded to deliver his inaugural address. He said that the age in which we lived was especially characterized by enthusiasm and push in every department of literature and science. Not alone had the special departments of the medical profession been advanced, but the art and science of medicine generally was advancing to further possibilities and higher acquirements in scientific investigation and discovery. If we looked back for half a century, and marked the steady and progressive steps in medical practice, the dissipation of crude views and absurd practices that governed the profession in those days, and noted what had been accomplished in this generation, an amazing advance on any other period of the world's history was found. Legislative enactments had done little or nothing to abate quackery or increase the interest in medical literature. Whatever was to be done must be done through individual action. The profession was competent, through its representatives in the State and county societies, to establish what should be the standard of attainment of those who were to be received into the ranks. A more complete and thorough preliminary education of young men who desired to enter upon the study of medicine was the first step in advancing medical education. A much higher standard of medical qualifications before the granting of a diploma was universally conceded and acted upon by the leading medical colleges in the country. These requirements, if carried out, would, in the future, tend to bring about the desired result. The graded course of instruction in use at the University of Pennsylvania, Harvard College, and Syracuse University commended itself to consideration as the most systematic and approved method. The law passed in 1872 creating a State Board of Examination, whose duty it should be to certify to the qualifications of candidates for admission to practice, should be made compulsory and com-

prehensive, as it would remove all imputation of partiality or favoritism from any source. The proposition for the establishment of separate hospitals for contagious diseases in large cities should receive attention at the hands of the society and be carried into practical operation. The adulteration of food and drugs should also be considered.

The speaker suggested that the annual address be delivered in the hall where the meeting was held instead of at the Capitol. The philanthropic labors of the State and National Boards of Health were commended, but the work of the National Board was practically suspended by the remarkable disregard of the public health on the part of Congress in withholding supplies to carry on their labors. The subject should receive the considerate attention of the society, whose views should be emphatically expressed. The speaker devoted considerable space to a discussion of the new code of ethics, which, he said, had not been received by the profession or the medical press, in this and in other States, with cordiality or favor, but, on the contrary, by the most outspoken and emphatic opposition. A year's consideration, a calm and dispassionate discussion of the matter, had greatly enlarged the views of the profession in reference to the objectionable measure, and he trusted a more conservative sentiment existed to-day than at the time of its adoption. The objectionable clause in the new code consisted in the permission of consultation with any legally qualified practitioner of medicine, as not derogatory to the interest and dignity of the profession, or in cases of emergency, or where such aid was required upon the broad ground of common humanity. The advocates of the code held that this was only permissive and not obligatory, and the society should at this meeting consider the subject on its merits, and act as they might deem most conducive to the welfare, dignity, and interests of the medical profession of the State.

The President then announced the following committees:

Business—Drs. Alex. Hutchins, Kings County; C. C. F. Gay, Erie; Darwin Colvin, Wayne.

Credentials—Drs. E. V. Stoddard, Monroe; L. E. Felton, St. Lawrence; T. H. Squire, Chemung.

Dr. W. C. Wey, of Elmira, moved to take a recess for ten minutes.

Dr. S. O. VANDEPPOEL, of New York, moved to refer the President's address to an appropriate committee. The motion was carried.

A recess was then taken.

After the recess, the order of communications from county medical societies was announced, and the roll of counties was called by the Secretary, Dr. W. M. Smith, of Syracuse, but no communications were presented.

After the call, however, the County Society of Westchester presented a communication representing their loyalty to the American Medical Association, and deprecating the action of the State society in regard to the code.

Dr. D. B. St. John Roosa, of New York, moved that the communication be referred to the Committee on By-Laws, with a view to reprimanding the county society.

Dr. W. GOVAN, of Rockland, spoke in defence of the county society, and denominated the State society as secessionists.

Dr. Roosa repudiated the statement that the State society were secessionists. We had no relation with the American Medical Association. We sent delegates to it, but were not in any way connected with it. We did not propose to permit this society to be dictated to by any voluntary association.

Dr. ROCHESTER, of Buffalo, said we had adopted the code of the American Association.

Dr. Roosa replied: "And repealed it last year."

Dr. H. G. PIFFARD, of New York, moved that the communication be received and placed on file. Carried unanimously.

The Monroe County Society presented a communication which embodied a resolution urging the repeal of the new code.

Dr. MATRICE PERKINS moved that this and all similar communications be placed on file without reading.

Dr. DIDAMA, of Syracuse, asked how it could be known what the communications were unless they were read.

Dr. PIFFARD moved that the communications be referred to the Business Committee after being read.

Dr. ROOSA moved that these communications be read and placed on file.

Dr. DIDAMA objected very strongly to the First District's squeeling all these resolutions.

Dr. PIFFARD answered that the First District was not opposed to the reading of them.

Dr. J. S. MOSIER, of Albany, thought it would be better to defer these resolutions till later.

The motion that these communications and resolutions be read and placed on file was carried.

A communication was presented from Broome County condemning the course of the State society with reference to the new code.

Dr. J. G. CURTIS, of New York, read the annual report of the Committee on Experimental Medicine. It mentioned the adverse report by the committee of the Legislature of 1882 on Mr. Bergh's bill to prohibit vivisection. This was the third consecutive session of the Legislature at which the bill had been reported adversely. An association for Original Research had been established in Great Britain during the past year.

Last year one hundred dollars was set aside by the State society for the use of this committee, but it had not been found necessary to draw on it, as the expenses had been small. The committee recommended the adoption of a resolution favoring experiments on living animals.

A motion to receive the report and place it on the minutes was made and carried.

Dr. E. R. SUTTER, of Brooklyn, moved the adoption of the resolution recommended, and the continuance of the same committee for another year. Carried.

Dr. WEX, of the Committee on By-Laws, presented their report. It recommended the adoption of a resolution approving of the by-laws of the Warren County Society. The report was accepted, and the resolution adopted.

The same committee presented a communication from the society of Otsego County in regard to payment of dues. The committee recommended the adoption of a resolution that it was not expedient to modify the by-laws of this society. The resolution was adopted.

The committee also submitted a resolution that the several county medical societies which had not adopted by-laws should do so, and transmit copies to this society for ratification. In not more than seven instances were the by-laws of the county societies in harmony with the requirements of the laws of the State. The county medical societies were requested to submit their by-laws to the State society for the purpose of ascertaining whether they were in conformity with the laws of the State.

Dr. DOUGLAS's motion that the communication be taken on the table for future action was lost.

A motion that the communication be received and the resolution be adopted was carried.

A communication was received from the Oswego County Medical Society, containing the resolution adopted by them, that in regard to the ethics of consultation it is unworthy of us to call into consultation any but regular practitioners. The communication was received and placed on file.

Dr. SUTTER submitted the following propositions and resolutions:

Whereas, The Special Committee on the Code of Ethics, in its report at the last annual meeting, recommended a change in one part of the code which was more in the nature of a revolution than of a revision, and, therefore, may be more radical than was expected or desired by the constituency of this society; and

Whereas, That report was adopted at a session wherein only fifty-two members voted in the affirmative, and thus legislated for the entire profession of the State on a subject of vital importance in a direction which may not have been anticipated or desired by the profession at large; therefore,

Be it Resolved, That all the action taken at the annual meeting of 1882, in regard to changing the Code of Ethics, be repealed, leaving the code to stand as it was before such action was taken.

Resolved, That a new special committee of five be nominated by the Nominating Committee of the society, and be appointed by the society to review the Code of Ethics, and to report at the annual meeting of 1884 any changes in the code that may be deemed advisable.

Resolved, That the report of this committee be discussed at the meeting of 1884, and be then laid over for final action at the meeting of 1885.

He moved that the resolutions be made the special order for the evening session at eight o'clock.

Dr. PERKINS moved that the hour of the meeting be half-past seven instead of eight. Carried.

The Business Committee called the attention of the society to the resolution of 1882, limiting the time for the reading of papers to twenty minutes, and suggested that, when this could not be done, abstracts should be read instead of the entire paper.

Dr. SQUIBB thought it would be better to give the committee discretion to extend the time, unless there was a press of business.

The SECRETARY thought the matter might be best arranged by leaving it to the Business Committee.

Dr. SQUIBB feared that that would throw too much of the onus on the Business Committee. Dr. Squibb's motion was carried.

Dr. PIFFARD then read a portion of a paper on ACNE.

Dr. C. R. AGNEW, of New York, one of the delegates of the State society to the American Medical Association, made a report to the effect that, on presenting his credentials at the annual meeting of that association, they were rejected, one member of the State society being conspicuous in the association by his attempts to interest its members against the admission of the delegation. Dr. Agnew also read a letter from Dr. Sayre, one of the State society's delegates, declining to serve, on the ground that he considered the society's departure from the code of the American Medical Association as unwarranted and unauthorized.

The report gave rise to a discussion, but was finally received.

Dr. SAMUEL SEXTON, of New York, read a paper on the REMOVAL OF FOREIGN BODIES FROM THE EAR. [This paper will appear in a future number of the journal.]

Dr. B. L. Hovey, of Rochester, was appointed a member of the Business Committee in the place of Dr. Colvin, who was absent.

In the discussion on Dr. Sexton's paper, Dr. ROOSA said there were many questions generally supposed to belong to the province of the specialist that really belong to the general practitioner. Take, for instance, the disease known as mumps. Specialists saw the cases after the disease had run its course. The same rule held good in regard to foreign bodies in the ear.

The general practitioner was the man who would see these cases at the time when they could best be relieved. He deemed it a misfortune that this *armamentarium* of instruments should be exposed here. When a child was seen immediately after a bean had been pushed into the auditory canal, then was the opportunity for ordinary successful and easy treatment, and that treatment was by the use of one of the simplest and most effective means that any man could employ—viz., the use of the syringe and warm water. A case was rarely seen which could not be controlled by these means. When the foreign body had been pushed down, surgical skill was needed. He believed that the worst treatment was the use of forceps, and the best the employment of Dr. Gross's simple hook and spoon. It seemed to him a mistake to begin with instruments.

Dr. H. KNAPP, of New York, agreed with Dr. Roosa. His experience with the eye convinced him that the use of forceps was objectionable, and he exhibited two forms of curette, one a single- and the other a double-bladed spoon, and remarked that the principal objection to them was their width.

Dr. GRUENING's experience convinced him that the syringe and warm water were the best means of treatment in these cases.

Dr. A. H. SMITH, of New York, remarked that Dr. SMITH, of Nyack, had suggested the use of some rapidly drying adhesive substance to cause the adhesion of a string or camel's-hair brush to the foreign body.

Dr. DAVID WEBSTER, of New York, thought that no one should attempt the removal of a foreign body unless it was visible.

Dr. A. H. MATHEWSON, of Brooklyn, remarked that foreign bodies had been known to remain for a long time in the ear without doing any particular damage. He had known a case in which a foreign body had been in the ear for a period of seven years.

Dr. SEXTON stated that his paper was prepared with the impression that the members of the society possessed the intelligence which had been shown, and would use the instruments skillfully.

HOT WATER AS AN HÆMASTATIC.—Dr. W. B. CHASE, of Brooklyn, read a paper on this subject, in which he said that in many minor operations the flow of blood was the principal difficulty to be met. Washing a stump with cold water after an amputation increased the cutaneous congestion, and hemorrhage was likely to follow. The application of hot water would arrest the flow of blood. The local application of hot water arrested the flow of blood in traumatic and in some forms of idiopathic hemorrhage.

The *modus operandi* of the immediate effect of hot water was difficult of explanation. It must be attributed to some action on the vaso-motor nerves. The method of using hot water, as employed by him, was by sponging; or, in the case of uterine hemorrhage, by syringing. The water should be of a temperature varying from 115° to 130°. In the latter class of cases its effects were prompt and salutary. In the removal of intra-uterine growths it was invaluable.

Afternoon Session.

Dr. G. H. Fox, of New York, read a paper on the treatment of urticaria, in which he stated that the treatment must vary with the cause of the disease. When dependent upon a gouty diathesis, such remedies as carbonate of sodium and colchicum were proper, with abstinence from meat and nitrogenous food. In gastro-intestinal disturbances, rhubarb, bismuth, and sulphurous acid were indicated.

Flatulence was often the only sign of indigestion. In a case of obstinate urticaria with frequent relapses, treated, according

to the suggestion of Dr. J. M. Da Costa, of Philadelphia, with sulphurous acid with alkaline baths at night, a notable improvement occurred on the second day, and a cure without subsequent relapse was accomplished by the end of the second week.

Drugs which acted upon the nervous system, such as quinine and others, had both caused and cured urticaria. Some patients were intolerant of quinine, and invariably suffered from its use.

Dr. F. D. LENTE had noted cases of malaria ushered in by premonitory urticaria. In one peculiar case the urticaria appeared every evening at seven o'clock, and was cured by ten-grain doses of quinine.

Belladonna and atropine had been used in doses sufficient to produce flushing of the face. The reader—Dr. Fox—had seen less benefit from atropine than from belladonna.

Salicylate of sodium in doses of one grain every hour had relieved the disease, but larger doses had more frequently produced it.

The use of arsenic had given rise to contradictory reports. Bromide of potassium had been effective. Drop doses of copaiba had been used in vain by himself as well as by others.

The use of these various remedies, and of half-drachm doses of ergot, showed that the treatment of urticaria was empirical, and the good results reported were often attributable to careless observation and to self cure. The proper treatment depended upon the etiology.

Dr. ROCHESTER stated that he had seen a good deal of urticaria, and had found that an emetic such as ipecac was much more efficacious than other remedies. It was possible that the diaphoretic action had something to do with it. He had placed a patient upon a simple milk diet, taking four or five quarts a day, with much benefit.

The report on prize essays was then made. But one essay had been presented, the title being Cancer. The committee making the report stated that the essay was well written, but its author, by quotations from a previous prize essay which he had written, had revealed his identity and had thus debarred himself from receiving the prize.

Dr. Rochester moved that prize essays be printed in future. The motion was carried.

Drs. Hutchinson, Strong, and Ely were announced as Committee on Inaugural Address.

The PRESIDENT then announced as *Nominating Committee*—1st district, Dr. F. A. Castle, of New York; 2d, Dr. P. R. II. Sawyer, of Westchester; 3d, Dr. M. Perkins, of Schenectady; 4th, Dr. Conant Sawyer, of Essex; 5th, Dr. J. D. Spencer, of Jefferson; 6th, Dr. George Douglas, of Chenango; 7th, Dr. H. D. Didama, of Onondaga; 8th, Dr. F. E. Hoyer, of Erie; and Dr. S. O. Vanderpoel, of New York, from the society at large.

THE PATHOLOGY AND RADICAL CURE OF HAY FEVER.—Dr. J. O. ROE, of Rochester, read a paper on this subject, in which he reviewed the theories of the disease, viz.: The pollen theory of 1819; the view of Helmholtz of 1868; the animalcule theory of Salisbury of 1873; and the nervous theory of Dr. Beard, in which the effect was mistaken for the cause.

Dr. Blakeley had shown that the pollen of all plants—especially of the graminaceæ—would excite the disease; and that less than $\frac{1}{100}$ of a grain was sufficient.

A common cause, in a susceptible patient, was any variety of dust; thirty forms of "diversified invisible pastiness," as Tyndall called it, had been enumerated.

The recurrence of the disease upon the same day and hour in each year indicated pollen as a cause, as botanists had shown that the ripening of plants occurred yearly with great precision.

The mucous membrane covering the turbinate bones was a form of erectile tissue, and might be styled turbinate corpora cavernosa. Irritation of this tissue was reflected to the trachea and other distant organs. In five cases in which this erectile tissue had been removed, radical cure had resulted.

In the discussion, Dr. Wray asked Dr. Roe what method he employed in removing the hypertrophied tissue. Dr. Roe replied that he used the galvanic cautery or the wire écraseur.

Dr. SABIN, of Troy, remarked that he knew a lady who had a severe attack of hay fever every year, until her removal to Iowa, where she had been for several years entirely exempt from the disease.

Dr. Roe replied, "She left the cause of the disease."

Dr. PROT, of Brooklyn, stated that he had obtained good results from the application of chromic acid to the nasal mucous membrane, using bicarbonate of sodium immediately after.

Dr. GREEN, of Homer, referring to the effect of the pollen of rag-weed in cases of hay fever, stated that in his neighborhood rag-weed grew in abundance, and that, while some patients left there for relief, others came to Homer for the same purpose.

A NEW WAY OF APPLYING REMEDIES TO THE EYE.—Dr. W. F. MITTENDORF, of New York, read a paper on this subject. Solutions of the alkaloids in simple water were hard to keep, being liable to develop fungous growths. The use of granules might irritate or injure the cornea, and their solution took time. Vaseline was bland, but was applied to the eye with difficulty, and powders mixed with it might settle. Eserine, in particular, was hard to mix with vaseline. He preferred the use of impalpable powders, but it was difficult to find a vehicle which would dissolve readily in the eye. Starch, dextrin, sugar, and sugar of milk were for different reasons found objectionable. He had found powdered gum arabic with sugar of milk satisfactory. Eserine, which was deliquescent and gelatinous, was first dissolved in water, then mixed with sugar of milk and reduced to a powder, and then rubbed up with gum arabic. The various alkaloids thus prepared were, as a rule, to be used by the physician only. They could be dissolved in water in a watch-glass, or used dry. They could be dispensed in solution in water, when left for the patient to use.

The speaker then showed an EYE SPECTRUM, which could be expanded by means of a slide on projecting arms, which might be vertical or horizontal.

Dr. T. R. POOLEY, of New York, objected to what had been said against the use of vaseline, which he had found serviceable.

Dr. D. B. ST. JOHN ROOSA had never regarded fungi in solutions for the eye as in any respect harmful.

Dr. SQUIBB said that salicylic acid, which was soluble in three hundred parts of water, prevented the growth of fungi. Fungi subsisted at the expense of the alkaloid, and hence weakened the solutions. The difficulty with eserine could be overcome by using the salicylate of eserine, which did not deliquesce, and was not subject to attacks of fungi. Vaseline was not a good excipient, as it would dissolve nothing. Oleic acid was preferable, and the oleates of the alkaloids were soluble.

Dr. ERIC GREENING, of New York, said that he found it useful form in a saturated solution of boric acid, which was of itself bland, and in which the sulphates of alkaloids were soluble.

Dr. MITTENDORF said that the advantage of mixture with powdered gum arabic was that it could be weighed accurately.

Dr. POOLEY limited his use of vaseline to applications around the eye, but not in the eye.

SYRINGS OF THE LACRIMATOR.—Dr. DAVID WILSON, of New

York, read a paper in which he said that autophony seemed to be a symptom of such disease. He related two cases, characterized by nocturnal pain—both remarkable on account of the recovery of hearing. The voice, to others normal, sounded to the patient himself as if he were speaking into a barrel. Other collateral symptoms of syphilis existed in each case, and the treatment was anti-syphilitic, large amounts of mercury and iodide of potassium being used.

SYPHILITIC INFLAMMATION OF THE MIDDLE EAR, LABYRINTH, AND ACOUSTIC NERVE.—Dr. O. D. POMEROY, of New York, read a paper in which he said that rapid or sudden loss of hearing was characteristic of a syphilitic affection, which was often painless. There might be nocturnal pains extending down the arms. Double vision and strabismus, affections of the facial nerve, hemiplegia, and paraplegia might occur. Ordinarily there was no discharge from the ear, but occasionally there was suppurative otitis, with perforation of the membrana tympani, caries, and gummata. The drum membrane was usually dry, and a little reddened, and with infiltration, causing more opacity than in ordinary inflammation. It was difficult to locate the lesion. It was usually in the middle ear, and it was hardly justifiable to use the term labyrinthine disease, except after an autopsy. Syphilis was to be suspected from its collateral symptoms, and from the effects of treatment. In syphilitic disease the infiltration was out of proportion to the amount of inflammation. Vertigo and nausea were not characteristic.

Dr. HENRY W. WILLIAMS, of Boston, was introduced by the Business Committee. Dr. Williams said: "We came here to see how you do, and to enjoy for ourselves the privilege of meeting the chosen delegates of the Empire State. I congratulate the society for the success which it has already attained."

Dr. B. F. UPHAM, of Vermont, was then introduced, and spoke of the interest manifested in his State with reference to the workings of the New York State Medical Society, particularly during the past year, in the disposal of the question of Medical Ethics.

Dr. ROOSA thought that the differentiation of disease of the middle ear from labyrinthine disease was important. Disease of the middle ear was more amenable to treatment. It was not rare to find both parts diseased at once, and these mixed cases were not easy to determine. Absolute deafness, as noted by the author of the first paper, was an important guide. The note C of the tuning-fork, where there was still some hearing, was heard well through the air, but not through the mastoid. We had also a guide in a subjective symptom—the deaf often heard well in a noisy place. Instances of this fact were given by Dr. Roosa, which would indicate disease of the middle ear.

Dr. HOWELL, of Buffalo, regretted that the whole paper had not been heard. In these cases it was difficult to say how much was cause and effect, and how much mere coincidence.

Dr. SEXTON had observed that in many cases the patient, after hearing well at a given time, suddenly became autophonus after an act of swallowing. He had seen no suppurative case, no eye complications, and no recurrent attacks, as mentioned by Dr. Webster. Vertigo and tinnitus aurium had not been persistent.

INFUSION OF JEQUIRITY (*Abrus precatorius*) IN INVETERATE PANNUS.—Dr. GRUENING had employed infusion of jequirity, after the formula used as a cosmetic in Brazil (thirty-two beans being infused in 500 grammes of cold water for twenty-four hours, then, after adding 500 grammes of warm water, filtered after cooling). This solution applied topically, as recently practiced by De Wecker, caused an inflammation and the subsequent disappearance of granulations, the application being painless and free from certain objections that had been urged against gonorrhoeal inoculation. He had found it necessary to use the

fresh beans, as an infusion from the old ones proved inert. Cases were related of prompt and radical benefit from the treatment. The applications should be continued for about five days, and on their discontinuance the inflammation caused by them subsided promptly. During the first day there was no change; on the third day the conjunctiva was swollen, and the cornea became more opaque from increased vascularity; on the fifth day the opacity or the granulations disappeared.

A NEW TONGUE-SPATULA.—Dr. L. ELSBERG, of New York, reminded the meeting that, nineteen years ago, he showed the society a tongue-spatula which at that time he considered as scarcely calling for further change. The tongue-spatula, he remarked, was an instrument with which almost every one had found fault, and the handle of an ordinary spoon would serve quite as well as most of the many varieties of the instrument now in the market. The spatula he had formerly shown he had afterward found to be too wide, consequently pressing on the anterior palatine folds and causing nausea; moreover, the angle formed by the blade and the handle should be obtuse, instead of a right angle, as in the instrument formerly shown. The spatula now shown measured ten inches in length. The two blades might be either jointed or fixed. Each blade formed an arc of quite a large circle, and was fenestrated for the insertion of an instrument for the fixation of the jaws. One blade was an inch wide, and the other half an inch. In the use of the instrument it was not proper to push downward and backward, but to pull from behind forward, and from below upward.

A SINGLE CASE OF OVIOTOMY.—Dr. DAVID LITTLE, of Rochester, related a single case of ovariectomy, which, he thought, demonstrated the uselessness of Listerism and the paramount importance of strict cleanliness and free access of fresh air to the patient during the after-treatment. In the case related, the windows were left open, and the admission of sunlight was well provided for. The reader laid much stress on these precautions.

Evening Session.

Dr. SQUIBB moved that the meeting go into Committee of the Whole on the special order of the evening, his idea being to promote freedom of debate. The motion was carried.

Dr. A. HUTCHINS, of Brooklyn, was called to the chair. The Secretary read the resolutions offered in the morning session by Dr. Squibb.

Dr. S. O. VANDERPOEL, of New York, moved that no one be permitted to speak on the question unless his name had been registered. The motion was carried.

Dr. Squibb said, in assuming the responsibility of these resolutions, some explanation was required. The medical profession of this State is associated into societies under and in pursuance of the laws of the State. The first section of the law organizes the county societies. The second section creates the Society of the State of New York. By authority of this law both the primary and the secondary bodies make by-laws for themselves. The constitution adopted by the society was called the Code of Medical Ethics. It becomes the supreme authority of this State, and the analogue of the civil constitution of the State. There is one, and only one, way in which a change can be made in the constitution. It must originate as a proposition only in the secondary body, and be ultimately decided in the primary bodies. If the Legislature of the State should adopt a new constitution without submitting it to the people, it would be denounced as an act of usurpation. The committee was appointed last year to suggest amendments. This committee reported not suggestions, but a substitute for the former constitution. Just here the irregular and unlawful action of the committee began. They pressed the report upon the society for immediate action.

(To be concluded.)

NEW YORK ACADEMY OF MEDICINE.

A STATED meeting was held December 21, 1882, FORDYCE BARKEE, M. D., LL. D., President, in the chair.

THE NORTHWESTERN MEDICAL AND SURGICAL SOCIETY presented to the Journal Fund of the Academy the sum of one hundred dollars.

Dr. AUSTIN FLINT presented, on behalf of Mr. James Platt White, a marble bust of the late Professor JAMES PLATT WHITE, of Buffalo, and offered the following resolution, which was seconded by Dr. Thomas:

"Resolved, That the New York Academy of Medicine accepts with much gratification the marble bust of the late Professor James Platt White, and accords to it gladly a permanent place in the hall of the Academy."

The gift was accepted by the President in behalf of the Academy.

Dr. T. GAILLARD THOMAS then read a paper entitled A CONTRIBUTION TO THE SUBJECT OF THE REMOVAL OF THE UTERINE APPENDAGES (TAIT'S OPERATION) FOR RECURRENT PELVIC INFLAMMATIONS: WITH PATHOLOGICAL SPECIMENS. [Dr. THOMAS'S paper appeared in our issue of January 13th, p. 32.]

GASTRO-ELYTROTYMY (THOMAS'S OPERATION) COMPARED WITH OÖPHORHYTECTOMY (PORRO'S OPERATION).—Dr. HENRY J. GARIBOUES read a paper with this title, in which he stated that, since four years ago, when he wrote a monograph on gastro-elytrotymy, this operation had been performed three times for the delivery of women, and once for the removal of a large calcified fibroma of the uterus; previous to that date the operation had been performed four times. From the eight operations there had been four recoveries and four maternal deaths. The chief objection to gastro-elytrotymy seemed to be that it could not be carried out according to the strict rules of antiseptic surgery; but, since the percentage of deaths in Porro's operation had been greater than that in Thomas's, would it not be well, he asked, to give the latter operation a fair trial? Moreover, although gastro-elytrotymy did not admit of the application of Listerism in all its details, yet great benefit might be derived from the rules laid down by Lister, as regarded the disinfection of the hands, of the instruments, etc. Attention was directed to the danger of hæmorrhage in the two operations, it being much greater in Porro's than in Thomas's. Reference was also made to the means which had been resorted to for controlling hæmorrhage when it had occurred, such as the use of the elastic ligature, of the écarneau, the soft rubber tube of Esmarch, etc. The danger from shock was less in gastro-elytrotymy than in Porro's operation, while danger from exhaustion was greater in the latter operation on account of supuration, which almost inevitably occurred. Peritonitis, which was the greater danger in Porro's operation and in Cæsarean section, was not likely to occur in gastro-elytrotymy. Several accidents were mentioned which were liable to occur in either operation, such as heart-clot, pulmonary oedema, tetanus, etc. The intra-peritoneal method of treating the stump in Porro's operation had not in the least increased the percentage of recoveries; out of five cases in which it had been adopted, four of the patients died. One advantage possessed by oöphorhysterectomy was the fact that it could be done before dilatation of the cervix had taken place, and before the patient had lost any strength in ineffectual efforts at expulsion through the natural channel. In most cases, however, the patient was not seen until after she had been in labor for some time. Porro's operation required many assistants, and made the woman sterile at once, while gastro-elytrotymy required a less number of assistants, and allowed of the bearing of three more children at least. The surroundings of the patient should not be left out of consideration. He would not hesitate to do the Cæsarean sec-

tion in the country even without any assistants. In hospital practice, however, he would prefer to do Thomas's operation if the cervix were dilated or dilatable. If it were necessary to operate before dilatation could be effected, Müller's operation should be adopted. The general condition of the patient might indicate one operation in preference to the others.

To summarize: 1. Thomas's operation, or gastro-elytrotymy, had been performed eight times, one half of the mothers recovering, and all of the children surviving except two, which were dead before the operation.

2. Gastro-elytrotymy might be performed with many antiseptic precautions.

3. Porro's operation had given less favorable results than gastro-elytrotymy.

4. The danger from hæmorrhage, peritonitis, and septicæmia was greater in the Porro-Müller operation.

5. The intra-peritoneal method of treating the stump in Porro's operation had been carried out in five cases, resulting in death in four cases.

6. One of the advantages of the Porro-Müller operation was the possibility of operating before the commencement of labor.

7. Gastro-elytrotymy was less repulsive to the mind of the patient, and less difficult of execution, and could be performed with less assistance. It did not render the woman sterile. All those who had performed it on the living subject or on the cadaver recommended it.

8. In country practice, the old-fashioned operation of Cæsarean section was in most cases preferable to any of its substitutes.

Both papers being before the Academy, Dr. WILLIAM M. POLK remarked that, if there yet remained anything to be said upon the subject of gastro-elytrotymy, it was, in the first place, with reference to placing the operation; and, in the second place, to disabuse the minds of its opponents with regard to the supposed difficulties in its performance as compared with Cæsarean section, Porro's operation, or Porro-Müller's modification. With regard to the position which the operation should take, he believed that it was a mistake to put it in direct antagonism to Cæsarean section, or any one of its modifications. There were indications for the Cæsarean operation, or some one of its modifications, in certain cases, which rendered it the only operation which could properly be performed. On the other hand, Cæsarean section, or some one of its modifications, had heretofore been performed in certain cases in which it should to-day give place to gastro-elytrotymy. For instance, in cases in which the child could not be extracted through the cervix for want of dilatation or other cause, Cæsarean section, or some one of its modifications, must necessarily be adopted. With regard to the difficulties of the operation, Dr. Polk traced in detail the successive steps to be taken in both gastro-elytrotymy and the Porro-Müller operation until the child was reached, comparing the difficulties and the dangers of the one with those of the other. One danger attending Porro's operation which did not exist in gastro-elytrotymy was the possibility of finding a coil of intestine in front of the uterus. Again, there was great danger of peritonitis arising from the necessity for entering the peritoneal cavity. There was also much greater danger of hæmorrhage after the uterus had been reached than in gastro-elytrotymy. The liability to injury of the epigastric artery, of the bladder, of the ureter, of the vessels of the broad ligament, and of the uterine artery, in gastro-elytrotymy, was slight, and, if it should happen, it need not be attended by any serious consequences. If necessary, the incision in gastro-elytrotymy might extend from any point between the crest of the ilium and the last rib to about an inch and a half above and within the spine of the pubes. A cutting instrument should not be used after

the transversalis fascia had been reached. He believed that the greatest difficulty attending this operation related to tilting the uterus sufficiently to allow of the extraction of the child. Dr. Polk also referred to the method of entering the vagina in gastro-elytrotomy, to the relation of the pelvic organs to one another at full term, to the method of closing the external wound and inserting a drainage tube at the lower angle to extend into the vagina, etc.

Dr. ISAAC E. TAYLOR stated that since 1870 there had been four different operations devised to take the place of Cæsarean section, aside from that of gastro-elytrotomy—viz., that of Baudelocque, Porro's operation, and that of Taylor and Sanger. Notwithstanding these numerous substitutes, Dr. Taylor believed that, when the conditions were favorable for the old classical operation of Cæsarean section, and it were possible to perform it early, the results would be better than from any other method which could be adopted. He then reviewed the statistics of the Porro operation, of Cæsarean section, and of gastro-elytrotomy, and stated that in the case of the first- and last-named operations the percentage of successes had been about one half, whereas in Cæsarean section, unless performed under the most unfavorable conditions, the percentage of successes had been greater. He was of the impression that when, in addition to the dangers and difficulties already mentioned as attending gastro-elytrotomy, we considered the possibility of having yet to perform embryotomy, turning, etc., it would be found that Porro's operation possessed many advantages, and, in certain cases, should be preferred; but, in general, Cæsarean section should be adopted. In the infantile pelvis, the equally contracted pelvis, and in that presenting the male form, he thought no other operation would offer prospects of as good results as would gastro-elytrotomy.

Dr. A. J. C. SKENE wished simply to make one remark with reference to his case, which had been mentioned by Dr. Garrigues in his paper. That was, that the patient really died of exhaustion, the result of previous operations, and not of shock, the result of gastro-elytrotomy. He thought it was an abuse of statistics to use them in comparing gastro-elytrotomy with Cæsarean section and its modifications before the former had had a more extensive trial than had yet been given it. The possible obstacles to be met with in the extraction of the child, as alluded to by Dr. Taylor, had no existence in fact. He felt convinced that, when gastro-elytrotomy shall have had a fair trial, it would be found to possess infinite advantages over the other operations.

Dr. WILLIAM T. Lusk remarked that he had witnessed Porro's operation but once, and had never seen gastro-elytrotomy performed. Notwithstanding all of the advantages which had been expected from Porro's operation, the statistics showed a percentage of but forty seven recoveries to fifty-five deaths, and it was a question whether we could not properly say of it, as was said of Belshazzar, that it had been weighed in the balance and had been found wanting. Although he was of the impression that in suitable cases gastro-elytrotomy, possessed many advantages over the other operations, yet a more extended trial of the operation would be required before we could feel positive that it possessed in fact the superiority which had been claimed for it. There were cases, at any rate, in which it would be improper to perform gastro-elytrotomy, and it would be necessary to have an alternative. Did the old classical operation, he asked, deserve the abuse which had been heaped upon it? He believed that the bad results which had attended it during the last centuries were due to the fact that the operation had almost invariably been performed in hospitals, and under such conditions as would render death nearly a certainty. Statistics showed that in the cases in which the uterine wound had been sewed up the results had been as good as those in the

other operations. It was well known that two peritoneal surfaces healed readily, and it had been proposed to utilize this fact in order to get ready union of the wound in Cæsarean section, by dissecting up the peritonæum to a distance of about two fifths of an inch on each side of the incision into the uterus, and then take out a melon-shaped piece of the organ and close the wound with the peritoneal flaps between its edges.

Dr. WALTER R. GILLETTE remarked that the operation of gastro-elytrotomy was one of the simplest and easiest to perform of any in abdominal surgery, and he thought that any person witnessing it would feel convinced that it was attended by infinitely less danger than was Cæsarean section or its substitutes. Although the wound in the uterus might be sewed up after Cæsarean section had been performed, yet there was the liability, as after even normal labor, of failure on the part of the organ to contract, allowing the wound to gape and give rise to peritonitis.

Dr. T. ADDIS EMMET remarked, with regard to Tait's operation, that he had had no personal experience in its performance, nor had he seen it done. He had, however, seen a number of patients who had been operated upon by Mr. Tait, and in his laboratory there were as many as sixty specimens which had been removed probably within eighteen months. Dr. Emmet had wondered where all these cases had come from, and what was their explanation. Some years ago he made a great many post-mortem examinations at the Immigrants' Hospital, and found the condition described by Mr. Tait in not more than a dozen cases. He had asked Mr. Tait particularly as to what were the indications for the operation. He was unable to give any reply except that in all cases of chronic pelvic inflammation which did not get well within a reasonable length of time he opened the abdomen, and invariably found the Fallopian tubes to contain a large quantity of serum or of pus. Dr. Emmet had also been much surprised at the remarkable success of this operation as performed by Mr. Tait, and at the wonderful improvement of the patients. Notwithstanding these facts, he was not yet prepared to do the operation until there had been a little more light thrown upon the subject.

The discussion was closed by Dr. GARRIGUES, who remarked with regard to the modification of Cæsarean section, as referred to by Dr. Lusk, that he believed it had a limited field of usefulness. In the case in which he had performed Cæsarean section, it was found at the post-mortem examination, two days afterward, that union had taken place by first intention. It was well known that gastro-elytrotomy had been essentially performed many years ago by Ritgen and Baudelocque, but it had been so entirely changed by Dr. Thomas that we should accept it as his operation, and study the results from that date.

Reports on the Progress of Medicine.

QUARTERLY REPORT ON ORTHOPÆDIC SURGERY AND DISEASES OF THE JOINTS.

No. XI.

By CHARLES T. POORE, M. D.,

SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN.

THE USE OF HOT WATER IN INFANTILE PARALYSIS.—Mr. Lee ("Brit. Med. Jour.," Dec. 2, 1892) advocates the use of hot water, applied twice a day to the paralyzed limb. He states that by this method of treatment the limb retains its plump condition, and in its growth and development keeps pace with the sound limb. He does not, however, state the condition of the paralyzed muscles.

ON THE SELECTION OF CASES FOR FORCIBLE MOVEMENT IN THE TREATMENT OF STIFF JOINTS.—In a paper read by Mr. Adams before the surgical section of the British Medical Association on this subject (*Ibid.*, Oct. 7, 1882), he first defines what is to be included in this classification, namely, those joints that are rendered "stiff" by inflammatory thickening of the tissues external to the joint, including, however, the capsular ligament, and also those stiffened by inflammatory adhesions pressing between the articular cartilages. Cases of bony or fibrous ankylosis, properly so called, are not included.

He considers that the existence of the articular cartilage is essential to the restoration of useful and permanent motion. The healthy, or nearly healthy, condition of this structure may generally be inferred from the clinical history of the case. He makes the following classification, placing in order from the most favorable to the most unfavorable, for treatment by forcible movement:

I. Cases of traumatic origin in healthy constitutions, generally occurring in the adult.

II. Cases after rheumatic inflammation of the joint.

III. Cases of strumous disease of the joint.

IV. Cases of acute suppurative inflammation, of pyemic origin, and suppurative inflammation in the neighborhood of and extending into the joint.

V. Cases—suppuration upon muscular contraction.

CLASS I.—Stiff joints, of traumatic origin, are, as a general rule, favorable for treatment, and permanent useful motion is obtained in most cases, only one or two operations being required. In this class suppurative inflammation and ulceration of the articular cartilages are usually absent. This class he divides into: *a*, cases of stiff joints, occurring after dislocations which have been reduced; *b*, cases of stiff joint, or cases in which motion is very limited, in unreduced dislocations of long standing; *c*, after fracture into or in the neighborhood of joints; *d*, occurring after bruises, followed by inflammation of the joint.

CLASS II.—In this class, the rheumatic, as in the preceding, there is an absence of suppuration in the joint, and ulceration of cartilages, and useful motion may usually be obtained after one or two operations. Cases in this class may be arranged in the following group: *a*, Cases of stiff joint, occurring after acute rheumatic inflammation; *b*, occurring after gonorrhoeal rheumatism; *c*, occurring after chronic rheumatic inflammation. In some of these cases, of long standing, structural changes in the articular cartilages gradually occur, and the joint becomes so firmly ankylosed that no treatment will avail. Cases associated with articular enlargement, as in chronic and rheumatic arthritis; motion may be restricted by these changes, although the articular surfaces are smooth and polished.

CLASS III.—Cases belonging to this class, stiffness due to strumous disease, are essentially unfavorable for treatment by forcible movement, in consequence of the destructive character of the disease. Even when external abscess does not occur, the disorganization is usually complete, and either fibrous or bony ankylosis may be looked for. In only a limited number of cases, in which the disease has been arrested in an early stage, should any attempt be made to obtain motion.

CLASS IV.—Cases of stiff joint from pyemic origin, as well as those resulting from suppurative inflammation, commencing in the neighborhood of the joint, and subsequently extending to the articulation, are unfavorable for treatment.

CLASS V.—Cases of stiff joint due to muscular contraction should never be submitted to treatment by forcible movement. They will certainly yield to tenotomy and gradual mechanical extension.

He does not consider that either great force or any machin-

ery is ever necessary in the "breaking down" of joints. He has seen many failures—cases in which the joints have quickly re-stiffened, and complete bony ankylosis resulted, and he has never witnessed any good results which would justify the employment of such an amount of force. The accidents which have been known to follow the employment of an extreme degree of force are fracture of the long bones, separation of the epiphyses, transverse fracture of the patella, laceration of the ligamentum patella, rupture of the popliteal vessels, laceration of the skin, and also laceration of all the superficial structures. Mr. Adams adopts the gradual method in all severe cases, using at the first operation only just sufficient force to obtain the least possible movement, and then, at successive operations, repeated at intervals of from two to three weeks, tears through other adhesions, and gradually increases the range of motion, until the full extent is obtained. After each operation he applies hot-water dressings, and to the leg always employs weight and extension. Absolute rest is essential.

TREATMENT OF HIP-JOINT DISEASE.—Mr. E. Noble Smith (*Ibid.*, Oct. 28, 1882) draws attention to the defects in the splints generally used in the treatment of disease of the hip joint, in that they do not overcome the contraction of the psoas and iliacus muscles. From the line in which traction is made they increase rather than diminish the intra-articular pressure; and, although the limb can be brought down into an apparently straight position, it is at the expense of the lower lumbar vertebra, which are arched forward (lordoses). To obviate this, he advocates the use of an apparatus extending from the pelvis to the shoulder behind, with an abdominal band in front. This is to prevent tilting forward of the pelvis. In addition to the usual hip-splint, both portions of the apparatus are attached to a common hip-band. The movements of the hip portion are regulated by a double rack-joint.

THE EARLY TREATMENT OF FLAT-FOOT.—Mr. Bernard Roth (*Ibid.*, Nov. 18, 1882), in some remarks on flat-foot, adopts the following classification from Mr. Paget:

1. Cases in which it is possible to restore the foot completely to the normal shape, by passive manipulations, without any decided force being employed.

2. Cases where the tarsal bones have become more or less fixed in their displaced position by fibrous ankylosis, shortened ligaments, or osseous deformity, and which require more or less severe operative interference under anaesthetics.

3. Intermediate cases, in which partial restoration of the normal plantar arch is possible by passive manipulations.

He deals only with groups 1 and 3. He considers that the same constitutional relaxed habit of body that predisposes to lateral curvature of the spine also tends frequently to produce flat-foot. The restoration and maintenance of the plantar arch is most important. If the foot can be more or less completely restored to its natural position, boots, properly shaped to the feet, should be worn. The human foot touches the ground, not only at the heel and the lower surface of the metatarsophalangeal joints and the toes, but also by the whole outer border of the sole, for the width of one-half to one inch. It is hence essential that this portion of the sole should also touch the ground through the boot. Boots should, therefore, be made without heels. A wedge-shaped oval pad, with straight side forming the base, and corresponding in shape to the normal hollow of the plantar arch, is fixed inside the boot. Felt is the best material for the pad. In no case is the pad to extend across the "waist" of the boot, as this interferes with the normal transverse plantar arch. Laced boots only should be employed. The arch being preserved to a great extent by the action of certain muscles, the tibial and peroneal, these should be strengthened and developed by exercise, massage, etc. Atten-

tion should also be paid to improving the general health of the patient.

BONE-SETTING.—Mr. Howard Marsh (*Ibid.*, Oct. 7, 1882) concludes a paper on the cases usually benefited by bone-setters as follows:

1. There are a large number of cases in which manipulation proves itself one of the most successful methods in the whole field of minor surgery.

2. It is an error to regard manipulative treatment as necessarily a process of violence. In the majority of suitable cases it can be carried out with such slight force that the chance of doing injury is extremely small.

3. It is chiefly useful in cases in which healthy joints have their movements restricted, and are rendered painful by some external agency, such as—and very commonly—adhesions, or by rigidity of muscles, slipped tendons, and so forth. In the knee, however, internal arrangement must be carefully borne in mind.

4. We must remember how likely it is that adhesions will form after sprains, dislocations, and fractures, or after any injury leading to the exudation of lymph in the sheaths of tendons and other soft parts. We must prevent their formation—as far as we can—by gentle passive movements of the joint shortly after the injury, where this is possible. We must not keep joints too long fixed by splints and bandages, and we must not dismiss patients till we are sure no adhesions or rigid muscles remain to impede movement.

5. Manipulation will seldom do good; it will generally do harm in cases in which joints have been seriously diseased. In cases of firm fibrous ankylosis, it is quite unlikely to restore movement. It may, however, sometimes be employed to improve the position of the limb.

6. Joints that are fit for manipulation are those which, after injury, or the slighter forms of inflammation, are habitually cool and free from considerable synovial swelling, or which look quite sound, or around which the tissues are brawny and the skin pale, or indistinctly dusky, and in which movement within a limited range is free and smooth. Mere pain, if the joint be cool and there are no signs of serious disease, by no means forbids manipulation. On the contrary, it is a strong reason for using it.

7. A certain number of instances are met with in which no exact diagnosis can be made, but in which there is no evidence of structural disease, though the limb is stiff and disabled. In such cases, if manipulation be employed, an anæsthetic being given, and the limb being carried in all directions through its normal range of movement, we shall not rarely effect a cure, which, however, we may not be able to explain. Some of these are examples of hysteria, some deep-seated adhesions, some slipped tendons, and some simple muscular rigidity.

8. It is advisable, as a rule, to use an anæsthetic, not only to save the patient pain, but also, by relaxing the muscles, to bring the effort used to bear entirely on the source of abnormal resistance, whatever it may be. And, during manipulation, joints must always be flexed before they are extended.

9. We must often supplement manipulation with continued passive movements, douching, shampooing, etc.

10. Lastly, I will venture to refer to the importance of attending carefully to the minor affections about the joints. By being remiss in these cases we open the door to bone-setting, and are apt to commit oversights that we can not fail to regret.

Miscellany.

A NEW OPERATION FOR THE REMOVAL OF THE DEVIATED SEPTUM IN NASAL CATARRH.—Dr. W. C. Jarvis ("Arch. of Laryngol.," Oct., 1882), after describing some of the usual operations for the relief of nasal deformities of this kind, advocates a procedure of his own. The instruments used are his own wire snare écraseur, transfixion needles, and a peculiar scissors for excising portions of the septum. The écraseur consists of a long and short cannula, the latter gliding over a screw read cut on the former.

A milled nut, fitting this thread, is intended to push the outer cannula before it. Well-tempered steel piano-wire is drawn through the large cannula, and its ends are attached to the retention-pins on the small one. As the outer cannula can not turn, there is no twisting of the wire loop formed. The transfixion needles are pointed like the ordinary glovers' needles. Four sizes are made, running from one to four inches in length. Each number has a straight needle, and three others of varying curves. They are all furnished with a light, convenient handle. The septum scissors are light instruments with the blades curved almost at a right angle. Their shape enables the operator to obtain an easy view of the tissues to be removed. One instrument is made after the pattern of Richardson's mouse-toothed scissors; the other has a sharp beak upon the upper blade, which sinks into the tissue of the septum, and thus enables the scissors blades to retain their grasp while cutting through cartilage. A ring in the fixation blade is intended to slip over the middle finger, while the knob on the movable blade is managed with the thumb. This simple arrangement enables one to hook and divide the cartilage of the septum with great facility.

The amount of tissue to be removed is generally estimated by comparing the redundancy with the unaffected portion of the septum. This having been carefully determined, the base of the cartilaginous projection or hypertrophied tissue is pierced with the transfixion needle till the point reappears. The wire loop of the écraseur is now passed over the point of the needle projecting into the nostril, and tightened

around the transfixed tissue by forcing up the outer cannula with a movement of the finger against the milled nut. A few turns of the nut cause the wire to sever the transfixed tissue. When the posterior surface of the deviated tissue is not well defined, it is advisable to use a curved needle in order to bring its point to view. A little practice will enable one to determine when complete transfixion has taken place, by the change in resistance, appreciated by the touch where the point of the needle can not be seen.

The discomfort caused by this operation will vary with the patient's susceptibility to pain, and the amount of care used in manipulating the *écraseur*. Patients, as a rule, declare they do not suffer. A painless operation by this method may be converted into an agonizing one by the impatient movements of a rapid operator.

The hemorrhage is trifling if the operation is performed slowly. The employment of slow traction to prevent pain *goes against* hemorrhage. The vascularity of the mucous membrane over the septum is very slight when compared with that of the turbinated tissues.

Localized and general thickenings of the mucous membrane situated anteriorly upon the triangular cartilage can be readily removed. The localized hypertrophies found over the vomer are sometimes difficult to remove, as the tissue is transfixed and snared when pictured in the rhinoscopic mirror. When the thickened tissue is in contact with the outer wall of the nose, the author uses the transfixion needle, which has its point at right angles with the shaft. By successfully hooking and snaring off pieces of the septum, it is possible to make an opening into the posterior nares. The patient practice of this method has enabled the author to perforate even an imperforate nostril without connecting the nasal cavities by an undesirable opening.

Especially brilliant results can be obtained in relieving the common deformity produced by displacement of the cartilage of the columna. Nasal stenosis caused by a deviated cartilage is always overcome by the careful practice of this method without perforating the septum. This procedure is strongly urged to supply the now general practice of perforating the septum with a punch. The great objection to this latter operation lies in the collection of inspissated nasal mucus around the edges of the opening.

CURATIVE AND MODIFYING ERYSIPELAS.—Dr. H. Dauchez ("Union méd.," Oct. 5, 1882) seeks to show by certain facts the existence of a salutary erysipelas different in its results, but not in its nature, from ordinary infectious erysipelas. Thus, by the side of the erysipelas which kills the newly born and decimates the maternity hospitals of large cities there is another which may be called curative. The salutary action of erysipelas is shown by preference in certain chronic affections of the skin, which are all more or less rebellious to treatment. The modifying properties of erysipelas are sometimes strikingly shown in the cure of phagedenic chancre and of lupus; and also in certain old wounds, among which may be mentioned old ulcers of the leg, diffuse phlegmons with peritarticular suppuration, benign tumors of the breast in process of suppuration, etc. This salutary action is nothing else than the substitution of a more acute and more easily controlled inflammation for one which is chronic. To imitate in a just measure the action of nature is the object which certain physicians have proposed in combating lesions rebellious to all treatment, by transforming them through the agency of irritant medication. Trousseau has reserved the name substitutive medication to the use of irritants applied directly to the cure of local inflammations, which are cured by causing an analogous inflammation—a therapeutic inflammation substituted for a primitive irritation. Thus, certain ophthalmologists have sometimes used the virulent pus of a biennorrhagia for the cure of the conjunctival granulations of pannus. Dr. Champouillon reports a curious case of chronic bronchitis modified as to its place, if not absolutely cured, by the providential appearance of a pemphigus or an urticaria. In the same work there is also found the report of a case of varioloid attacking a man who had suffered for a long time from a rebellious psoriasis. The varioloid cured the psoriasis.

It is, however, especially in dermatology that substitutive medication finds its most frequent application. It is by provoking traumatic inflammation that scarifications cure lupus; and it is by greatly exciting the sebaceous follicles that lotions of sulphur and black soap

cure acne. The violent itching of lichen and prurigo is made to yield to frictions of the oil of cade, which acts by causing an inflammation of the skin.

There is, then, nothing astonishing in the fact that erysipelas excites the vitality of the skin, and that certain surgeons have even sought to excite an erysipelas in cases where all other medication has failed. Maurice Raynaud, in his article on erysipelas in the "Dictionnaire de med. et de chir. prat.," says: "A very important fact, to which I wish to call particular attention, is the very common development of erysipelas in persons affected with lupus. When this shows itself in the course of the treatment it is a very favorable circumstance. It is generally only slight in intensity, and is cured by the aid of an emetocathartic." The author gives the history of a case of his own in which an extensive lupus of the left cheek, nose, and lips was cured by an intercurrent attack of salutary erysipelas. Fournier, in one of his clinical lessons, cites an almost exactly analogous case, and the author has collected several others, all from good authorities and all very striking—cases of phagedenic chancre, of diffuse joint trouble with abscess and fistula, one of cancerous tumor (*sic*), and one of elephantiasis.

The author asks whether there exists an essential difference in nature between a salutary erysipelas and a grave erysipelas. In other words, does the bacterium punctum described by Orth and Bouchard exist in both? Unfortunately, he is unable to answer the question. His interesting communication is summed up as follows:

1. Erysipelas acts on a great many diseased tissues by exciting a lively inflammation, and by this irritative and substitutive action renewing their vitality.
2. It modifies favorably certain ulcers, particularly phagedenic chancre and lupus; it may also destroy certain fungous tumors, dry up old suppurations, and cause elephantiasis to disappear.
3. This salutary action is, unfortunately, rare, but it ought not to be misunderstood by physicians, and in the case of rebellious ulcers (scrofulous and syphilitic) it should be respected.

THE ALCOHOL QUESTION.—The public medicine aspects of the alcohol question were lately discussed by Dr. N. S. Kerr ("Brit. Med. Jour.," Sept. 23, 1882) in a paper read before the British Medical Association. The influence of alcohol on the public health is a vexed question, one party maintaining that all indulgence in alcohol during health is injurious; the other, that its use in moderation favors physical well-being and robustness of morals. Alcohol may induce disease directly or indirectly. Examples of the former are seen in delirium tremens, acute and chronic alcoholic poisoning. Examples of the latter are seen in the diminished resisting power to disease shown by people of drinking habits. The government return of the sickness and mortality of European troops in the Madras army for 1849 showed 11.1 per cent. of deaths among the total abstainers, 23.1 per cent. among the temperate, and 44.5 per cent. among the intemperate. The vital statistics of several life-insurance associations, orders of Sons of Temperance and friendly societies, show figures equally favorable to the total abstainers. In some of the life-insurance societies the total abstainers receive a larger proportionate share of the profits than the non-abstainers, being considered much more favorable risks. From investigations made by the author, the conclusion is reached that the annual mortality from "personal intemperance," in the United Kingdom, is not far from 40,500. About twice that number die from disease, violence, accident, or starvation caused by the intemperance of others. Noble, of Manchester, attributes one third of the disease in England to intemperance. In the various work-houses the allowances for stimulants has been gradually reduced, with no bad effect upon the health of the paupers. How to deal with the habitual drunkard is an important and perplexing question. Intemperance is the product of a physical agent, and produces a diseased condition of the system. The chief predisposing cause is heredity. There is but one means of cure—complete life-long abstinence from all intoxicating drinks. An interesting discussion followed the reading of the paper. Drysdale, of London, remarked that his observation led him to the conclusion that alcohol was one of the very commonest causes of death. He thought it would rank next to typhoid fever. In France, the most common cause of

death is alcohol. Carter, of Liverpool, observed that the fact that total abstinents lived longer than the so-called moderate drinkers was as well established as any undemonstrable fact could be. Scottiff, of London, remarked that the statistics of life insurance, as evidence of the beneficial results of abstinence from alcohol, harmonized with his own experience. The habitual use of alcohol as an ordinary article of diet is unnecessary for healthy persons. Medical men should have the courage of their convictions, and advise against intemperance. Darby, of Bray, thought that alcohol was valuable as a medicinal agent. The great increase in the consumption of aerated waters shows a movement in the right direction.

THE LEGAL RESPONSIBILITY OF MIDWIVES IN GERMANY.—Dr. V. Johannovsky ("Centralbl. f. Gynäk.," Nov. 18, 1882) relates a case which concerned a midwife who was brought to trial accused of having neglected to take proper precautions for the safety of those in her care. She had attended a woman who had given birth to a child by a breech presentation, and, instead of sending for a physician, had interfered herself, and, by unskillful and protracted efforts, had probably destroyed a fully developed child. This testimony was given by four physicians, yet the court could not possibly connect the neglect of the midwife with the death of the child *in utero*, and therefore acquitted her of the charge which had been preferred against her, but, upon the motion of the prosecuting attorney, yielded the indictment to the jurisdiction of the civil magistrate, before whom the accused might be tried for exceeding her instructions as a midwife. With regard to the deficiency of conviction on the part of the judges, with reference to the result which followed the midwife's conduct, the testimony of the physicians was not received at its full value. The mind which is untrained in the details of obstetrics can not form a valid opinion as to the influence in labor of physiological and pathological factors. The argument, according to the legal comprehension, concerning the ordinances which prescribe punishment, is that they have reference only to human beings which are already born into the world. So long as the fœtus remains *in utero*, according to the views expressed, there can be no discussion concerning negligence on the part of a midwife concerning the security to life of this person, because he is not yet a person, but a fœtus. Hence, the midwife is responsible only for exceeding her instructions as such. According to this view of the case, a midwife may do any amount of damage to the life and limb of the child, but is not criminal if only no harm comes to the mother. When the case is turned over to the civil magistrate, the testimony of the district or ward physician is elicited, which is often of little value, and a decision is rendered which will vary with the severity or mildness of the judge. The Austrian ordinance, in which are contained the instructions to midwives, was passed June 4, 1881, and, by a singular oversight, no penalty was fixed for violation of its provisions. The necessity is evident for a law which shall protect the fœtus, and place proper restrictions upon the midwife.

THE MEDICO-LEGAL SOCIETY.—At a recent meeting of the Medico-Legal Society, the President, Mr. Clark Bell, in his inaugural address, made the following recommendations:

I recommend that we invite all superintendents of hospitals, asylums, prisons, charitable institutions, municipal boards, judges, district attorneys, and especially all physicians in charge of any asylum or institution, to communicate direct to this society any case coming to their notice or under their observation involving medico-legal questions, with a brief and clear statement of the facts, and the forensic questions involved, with such comments, views, or criticism as they desire to submit to this body.

That this invitation be also extended to members of both professions throughout the United States, also to public officials, courts, or officers of justice, regarding medico-legal questions involved in actual cases arising: which questions, statements, or communications will be laid before the body, its permanent commission, or select and appropriate committees, for action.

The French Society of Medical Jurisprudence has adopted a similar plan with great success, and their later bulletins are enriched by reports of cases submitted by physicians and advocates throughout

France, which has sensibly widened the field of the labors of that body.

The increase in our membership of gentlemen carefully selected from the two professions, who take an interest in forensic cases, renders it possible for this society to ably respond to such practical questions as might be thus submitted, by subdividing the work among the members in select committees, while reports of cases or papers based upon actual facts arising from time to time (and often judicial decisions) would find an abler analysis and wider diffusion in the scientific world than through any other channel.

The public press of to-day finds our proceedings of increasing interest to its general readers, and our own publications will attract increasing public attention as time progresses.

I recommend that the Legislature be memorialized by this society in favor of the passage of a law:

1. Creating an officer to be known as the State Chemist, with a salary of not less than \$5,000, and not exceeding \$10,000 per annum, sufficient to secure the best talent in the State for the office.
2. That he have charge of a laboratory to be furnished by the State, with suitable assistants and facilities for operating the same under proper provisions.
3. That, in every case arising in the State calling for chemical analysis, the material be sent to this officer under proper regulations, and that his reports thereon be used in criminal cases for the people and the defense; and that this be placed upon such a basis, both as to the proper selection of an officer (who should be non-partisan), and selected only for high attainments in his profession, and its administration, as would enable the people and the accused to have the most careful chemical analysis made, in every case requiring one, at the public expense.

These recommendations were unanimously adopted.

ARMY INTELLIGENCE.—*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 20, 1883, to January 27, 1883.*—WATERS, WILLIAM E., Major and Surgeon. Detailed as member of Army Retiring Board, to convene at Fort Porter, Buffalo, New York, February 2, 1883. Par. 1, S. O. 21, A. G. O., January 23, 1883. — HEIZMAN, CHARLES L., Captain and Assistant Surgeon. Will be relieved from duty in the Department of the Columbia, and ordered to report to the Commanding General, Department of the South, for assignment to duty. Par. 10, S. O. 20, A. G. O., January 24, 1883. — KILBOURNE, H. S., Captain and Assistant Surgeon. Leave of absence for one month, with permission to apply for an extension of two months, is granted. S. O. 218, Department of Dakota, December 21, 1882. — PAICE, CURTIS E., Captain and Assistant Surgeon. Detailed as member of Army Retiring Board, to convene at Fort Porter, Buffalo, New York, February 2, 1883. Par. 1, S. O. 21, A. G. O., January 25, 1883. — SKINNER, JOHN O., Captain and Assistant Surgeon. Will report in person, at the expiration of his present leave of absence, to the Surgeon General for duty in his office. Par. 10, S. O. 20, A. G. O., January 24, 1883. — SPENCER, WILLIAM G., Captain and Assistant Surgeon. The leave of absence, on surgeon's certificate of disability, granted September 20, 1882, is extended three months on surgeon's certificate of disability. Par. 4, S. O. 16, A. G. O., January 19, 1883. — TAYLOR, MARCUS E., Captain and Assistant Surgeon. Will report in person, at the expiration of his present leave of absence, to the Commanding General, Department of the East, for assignment to duty. Par. 10, S. O. 20, A. G. O., January 24, 1883. — WOOD, MARSHALL W., Captain and Assistant Surgeon. Will be relieved from duty in the Department of the East at the expiration of his present leave of absence, and will report in person to the Commanding General, Department of the Columbia, for assignment to duty. Par. 10, S. O. 20, A. G. O., January 24, 1883. — WOOD, MARSHALL W., Captain and Assistant Surgeon. At expiration of present leave of absence, relieved from duty in Department of the East. Par. 1, S. O. 15, Department of the East, January 26, 1883. — WYETH, M. C., First Lieutenant and Assistant Surgeon. Is relieved from duty at Fort Snelling, and will proceed to Fort Stevenson, Dakota Territory, and report to the commanding officer of that post for duty. Par. 1, S. O. 15, Department of Dakota, January 18, 1883.

Lectures and Addresses.

A CLINICAL LECTURE ON
FIXATION OF MOVABLE KIDNEY.

DELIVERED AT THE NEW YORK HOSPITAL.

BY ROBERT F. WEIR, M. D.

GENTLEMEN: To-day I have something to show you which is out of the ordinary course, and which will present some notable points of interest. It is a condition which is not often seen, namely, a kidney that has been dislocated from its proper position, and has become so loosely attached that it now presses upon the neighboring abdominal organs in such a way as to interfere with their functions, and produce constant pain of such severity that the patient has been unable to perform the ordinary duties of life with any comfort, and has hence been obliged to give up work. The patient is a woman, thirty-three years of age, married, who has had several children, the last being now eleven years old. About five years since she was caught between two cars which were being pushed together by hand, so that they did not come together with very great force, and she then received quite a severe concussion of the abdomen in an antero-posterior direction. She was confined to her bed for only a brief period, and then resumed her ordinary work. But about five weeks after getting about again she began to complain of pain in the right side of the abdomen, which also ran down the thigh, and up toward the shoulders. Not long after this pain commenced, she, or the physician who attended her, she is not sure which, noticed a tumor appearing on the right side of the abdomen, and this seemed to be located at about the seat of her pain, which was increased by handling the tumor. Occasionally hæmaturia would result for a while, and sometimes a uterine hemorrhage would come on after an attack of severe pain. She has also had repeated attacks of vomiting and nausea. She has tried a variety of things to relieve herself, which have not succeeded, and, therefore, she has now come here a distance of over one hundred miles in order to seek a means of permanent relief.

This tumor of which she complains is a dislocated kidney, and it is a condition of affairs which is shown by statistics derived from autopsies, by those who are constantly making them, to exist in about one out of every seven hundred and fifty cases. But I think that the proportion of cases in which it occurs is really greater, for I myself have seen four such cases within the last year and a half. One very remarkable patient came in here some time since, with a movable kidney on the left side of the abdomen, and she said that some time previously a surgeon had tried to fix this lump to the abdominal wall by running a seton through it, and the only result caused by this operation was a little bloody urine. This kidney was subsequently removed in New Orleans, by Dr. Smyth, by an incision through the anterior abdominal walls. It is a curious fact that these floating kidneys are more frequently found on the right side than on the left, and they occur mostly in women. I have

copied a few figures from the statistics compiled by Landau,* who has given a good deal of attention to this subject. Out of 314 cases of movable kidney, he found 273 of them were in women, and of these, 152 were situated on the right side of the abdomen. This is not strange, for there are anatomical reasons for this increased frequency of the abnormality on the right side. One of the more important of these is that the renal vessels upon the right side are much longer than those on the left, and hence there is greater mobility possible on this side; and, again, the left kidney, besides having shorter vessels to sustain it, is pressed upon and held more snugly in position by the pancreas. Besides these, there are other lesser reasons which I have not now time to mention. Pregnancy, by elongating the mesocolon, and tight lacing have also been assigned as causes. It has been lately demonstrated that, aside from the pain caused by the pressure of the kidney on adjacent parts, the stretching and twisting, or kinking, of the long ureter will often cause a congestion and a damming up of the urine behind the point of obstruction, resulting in unpleasant symptoms. Some experiments of Kehrer, however, throw some doubt on this. There is another symptom of some value to us because of its medical aspect in some cases. From the pressure or dragging of the kidney upon the middle portion of the duodenum, certain obstinate dyspeptic symptoms and nausea or vomiting sometimes occur.

To relieve this condition of a displaced kidney, the first thing naturally thought of is to replace it, and this can easily be done by manipulation and pressure, the patient being in a recumbent position, and usually the kidney slips back into place with little or no pain, but in the present case considerable pain is then experienced. But the kidney can not easily be held *in situ*. A rubber bandage about the waist, or a large pad of adhesive plaster secured by a strap of the same material, or a specially constructed truss, is, however, sometimes successful. In the severer forms of this disorder, where these palliative means have failed, the question arises, Should this condition be relieved surgically? and, if so, then how can it be best treated?

Of late years a great deal has been said and written about the surgery of the kidney, and statistics of quite numerous operations have now been gathered. It has been shown that the mortality from nephrectomies is nearly fifty per cent. From a list of 100 cases recently presented by Dr. Harris, of Philadelphia, and from other sources, I find there have been eighteen nephrectomies, or extirpations of the kidney, performed for the relief of symptoms due to such displaced kidneys as this. Of these, two extirpations were made by the lumbar incision, and both patients recovered; sixteen were extracted by the abdominal incision, and seven recovered, while nine died. So the results of this operation are not very encouraging. Besides the danger from the operation directly, there is that incurred by the fact that in the majority of cases you are dealing with a floating kidney, which is only doing damage by its abnormal position, and hence an additional amount of work is suddenly thrown

*See Dr. Winkler's report, *Lancet*, 1881.

upon the remaining kidney. Again, you may, in your nephrectomy, be removing the only source for the elimination of urine. For in one case of operation of nephrectomy recently performed in this city, at the autopsy it was found that the patient had had only one kidney, and in another case, where a diseased kidney was removed, the remaining one existed only as a small cyst, the relics of a previous disease. This operation of nephrectomy is performed not only for displaced kidneys, but more frequently and justly for diseases of the kidneys, such as pyelo-hydronephritis, renal calculi, neoplasms, etc.

But only very recently in Berlin the question of the surgical treatment of a movable kidney has taken a different aspect. It is, according to Hahn, whether you can not relieve the patient by a safer operation than nephrectomy, namely, by cutting down in the loin upon the kidney, thereby avoiding the opening of the peritonæum, and, after reaching the capsule of the kidney, attaching its fatty and fibrous layers by sutures to the edges of the incision, and thus to hold or anchor the kidney in a new position, a little lower, perhaps, than normal, which will relieve the previous trouble; and this, too, by a comparatively harmless operation. This region is also selected for the incision because it is the safest one for the removal of the kidney, should it, in the course of the exploration, be found to be advisable. But, *en passant*, let me add that the lumbar incision for nephrectomy has one serious disadvantage, which is that you can not by it determine the existence of the other kidney. This can readily be done by the abdominal incision. What we yet need is a method to separate the secretion of one kidney from its fellow, and thus determine its condition. And in this connection I take pleasure in calling your attention to Dr. Sands's device of putting the hand into the rectum and pressing with two or three fingers over the region of one ureter, after emptying and washing out the bladder, and then collecting and examining the urine, presumably from the other kidney. There is yet another simpler plan which may be tried. You remember in the operation for amputation at the hip joint last week I used Davy's rod for pressing upon the common iliac artery to control the hæmorrhage. A similar instrument, with a larger flattened bulb at its extremity, might be employed for compressing the ureters. Both methods are, however, somewhat blind, as one can not be certain of recognizing the ureter, even by the fingers.

Another objection which has been offered to the major operation is, even if you remove one of the kidneys and the other is left still sound, are you not, as a consequence of the operation, exposing the patient to additional risks to which she should not otherwise be exposed? For when only one kidney is left to do all the work, there is danger of its suffering damage thereby. Thus, out of fourteen cases of solitary kidney which have been examined by Rayer and Mosler, calculi were found in the kidney in nine instances, and in seven of these death was caused by reason of these calculi. From interference with the circulation there is sometimes an increase in the amount of phosphates excreted, and these are liable to form stones, which may in cases of single kidney ultimately kill the patient.

In the "Centralblatt für Chirurgie" of July 23, 1881, and July 22, 1882, there are reported five cases of fixation, or anchoring, of the kidney, three of which were performed by Hahn and one each by Esmarch and Küster. In one of these cases there was a displacement of both kidneys, and two operations were resorted to, one four months subsequent to the other, and five months after the second one the patient was exhibited to the German Congress, cured. In the second case, great relief followed the operation, and in the third case the patient passed from under observation. In the two later cases of Esmarch and Küster the relief was great, but not complete. Though this operation has not been fully tested, yet I feel encouraged to attempt it, with good hopes of success, in the present case, rather than recommend or attempt a nephrectomy.

I propose to cut along the border of the quadratus lumborum muscle, not going too close to the twelfth rib, to avoid the pleura, as Holl directs, and divide all the tissues down to the mass of fat which should surround the kidney, and then stitch this to the edges of the wound, and so secure the kidney in a permanent position if possible. I will then leave the wound open and let it fill up with granulations, and finally cicatricial tissue will form in sufficient quantities to close the opening and support the kidney.

In this operation I shall use strictly antiseptic precautions throughout. For the spray, however, I will use the bichloride of mercury solution instead of carbolic acid, of the strength, say, of four grains of the bichloride to the pint. Under this spray the operation is comparatively safe, and although by mistake the peritonæum is opened slightly every now and then, yet I do not think this is of much importance if proper care is taken to keep the air about it pure, for in these accidents the gravity of the operation is, I think, not very much increased. Before proceeding to the operation, let me demonstrate the case to you.

As the patient's abdomen is exposed, you can see the manœuvre employed to cause the displacement to appear. I crowd the ribs inward, and the kidney is forced downward and toward the median line, and you can see its outline as it is grasped between the fingers. Its shape is distinct, of the size of a normal kidney, and it is felt lying with its long diameter across the right side of the abdomen, at about the level of the umbilicus, with its hilum looking upward; slight upward pressure causes it to slip into place.

Operation.—[The patient was turned over on her chest, with her face down, so that the right side of her back was most exposed, and over this the spray was kept playing. The back was then sponged off with a bichloride solution, and, after marking off a point three inches from the spinal column, Dr. Weir made an incision with a scalpel, passing vertically through this point and along the outer border of the quadratus lumborum muscle and extending from just below the lower border of the twelfth rib downward to the crest of the ilium. The first cut passed through the integument and subcutaneous areolar tissue and fat, and then by lighter incisions the sheath of the muscle was speedily exposed, and it and the superstructures were divided on a director until the region of the kidney was reached. A few bleeding vessels were meanwhile secured by forcipressure for-

ceps or torsion, and the parts kept clean by frequent sponging. The hemorrhage was insignificant in amount. After all the intervening structures had been divided, the edges of the wound were held apart by retractors, and, while the operator introduced his fingers to explore the cavity, the kidney was pushed into place by the hand of an assistant pressing upward through the anterior abdominal wall. By this manipulation the lower border of the kidney was first grasped, and then it was turned so as to expose the long diameter of the organ through the long diameter of the wound, and thus it was made visible to all in the room. Its mobility up and down amounted to nearly four inches. A portion of the capsule was next seized with the dressing-forceps, and held fast while a needle armed with a piece of carbolized catgut suture was passed through it and the areolar or fatty tissue investing the kidney, and then through the integument and deeper tissues near the edge of the wound, and the two parts were drawn tightly together and held in coaptation. Another similar suture was placed at about a distance of three fourths of an inch from the first, and so the fat capsule was united, by six or eight sutures, to the edges of the wound on all sides. But before all the sutures were passed, a drainage tube was inserted deeply into the lowest portion of the wound and secured there, and the redundant tissue investing the capsule was trimmed off by scissors, so that the body of the kidney might be held low down toward the crest of the ilium and snugly against the mouth of the wound. After all the sutures had been secured and the parts cleansed, a complete impermeable dressing of bichloride gauze, Macintosh, and bandages, was applied without closing the wound, which was intended should be closed by granulation tissue, and it was hoped that a sufficient amount of inflammation would ensue to throw out plastic material in such quantity as to ultimately hold the kidney securely in its new position. The operation and the dressing were completed in thirty minutes after the first incision was made.]

NOTE.—The patient did well. The wound closed in five weeks, and at this date, January 26, 1883, she is much improved in condition. The kidney is fixed in its new position, and she only has some hyperæsthesia along the course of the ilio-hypogastric nerve, due to damage done at the operation.

Original Communications.

CASE OF EXTIRPATION OF A DISPLACED KIDNEY.*

By WILLIAM M. POLK, M. D.,

PROFESSOR OF OBSTETRICS AND GYNAECOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

Owing to an unavoidable delay in the report upon the autopsy in this case, I have been prevented presenting it till to-night. The details of the case I now beg leave to lay before you.

In June last, a young woman was sent to the clinic of

the medical department of the university for examination and treatment. She was nineteen years old, unmarried, and, with the exception of the condition then present, had always been well. At seventeen years of age she began to menstruate. The flow was scanty, but more or less persistent for a week, coming away apparently when she urinated. During its continuance she suffered from pain in the left iliac region, and some back-ache. These phenomena, together with the flow, recurred a second time in about five weeks. After that she was free from disturbance for some months. Again the iliac pain and back-ache returned, and continued to return at intervals, varying from three to five weeks, till she came under our observation. Occasionally a flow of blood from the genitals would accompany these pains. Whether this flow was from the genital tract, the bladder, or the rectum, the patient was unable to state, but she thought it came away with the urine. A careful examination showed a fair state of general health, a complexion that would have been ruddy but for a slightly bluish hue about the lips. The heart, lungs, liver, and spleen were normal. The pulse in both wrists was better marked in the ulnar than in the radial arteries. The urine was normal in quality and quantity. The external genital organs were seen to be imperfectly developed, and the vaginal orifice was absent. In order that the pelvic organs might be thoroughly investigated, the patient was etherized. It was then found that the pelvis contained *nothing* but a bladder and rectum. In the left iliac region, deep in the fossa, was a tumor, freely movable in all directions. It could be pushed as low as Poupart's ligament, as far outward as the anterior superior spine of the ilium, far enough inward to bring its inner border to the center of the pelvic inlet, and far enough upward to bring its upper border a finger's breadth above the posterior border of the crest of the ilium. It was of oval form, its greatest length being from above downward and inward, its lower extremity apparently smaller than the upper. Running from this lower extremity downward into the pelvis, apparently toward the posterior surface of the bladder, was a thin cord-like strip of tissue.* The tumor, which had been discovered before etherization, coincided with the region of pain of which the patient first spoke. The right iliac fossa was found to be normal. From this it was evident that there was no vagina, and certainly neither uterus nor ovaries in the true pelvis.

The patient had come for consultation in reference to the deformity, and with a view to finding relief for the pain and distress referable to the left iliac fossa. Thinking it best to keep her under observation for a while, she was allowed to remain in the hospital (Bellevue) for the summer. On August 7th she complained of ~~the same~~ passing a small amount of blood with the urine that day. The tumor in the iliac fossa was enlarged and very tender, the back-ache was intense, and a ~~condition of general distress~~ prevailed. These symptoms lasted three or four days, then subsided. These phenomena were repeated in September, and again in October. As long as the patient remained in bed she was comparatively comfortable, but ~~was unable to get up and walking~~

* Read before the New York Obstetrical Society, February 6, 1883.

* See the report of the ~~autopsy~~ in the account of the autopsy.

about, the iliac pain was so severe as to make it necessary to keep her mildly under the influence of morphine.

The patient being urgent that some operative measure should be attempted for her relief, and thinking that the line of thickened tissue leading from the pelvic brim on the left side down into the pelvis might possibly be a rudimentary vagina, a slight incision was made into the tissue just below the meatus urinarius. This was deepened by means of the finger for about an inch. Nothing being found, the wound was dressed, and in a few days had closed. It was now explained to the patient that the creation of a genital tract was impossible. The question remaining was the possibility of relief from the iliac pain and the general incapacity which it occasioned, for it should be stated that, though this distress was most marked during the menstrual efforts, it was at all times sufficiently present to prevent her following any occupation capable of furnishing a means of livelihood.

This brought us face to face with the question as to the precise nature of the tumor. Of course, this question was considered in the first instance, when the exploration at the site of the vaginal orifice was made, but, as it has a more direct relation to the measure adopted for the relief of the pain, I think it will be less confusing to present the matter here.

Three opinions were entertained—one, that it was a displaced kidney; a second, that it was an ovary; a third, that it was a uterus. Carefully weighing all the reasons for and against, it seemed plain that we had to deal with a displaced kidney, but one that was intimately associated with menstruation—so intimately as to make it probable that there was a close relation between the organ and the ovary. The fact that all the menstrual symptoms pointed to the left iliac region and none to the right, that no enlargement or tenderness during menstruation could be detected in the right iliac region, suggested the idea that all the organs appertaining to that function present in the case were in the left side. The line of thickened tissue that seemed to extend from the inner edge of the tumor down into the pelvis between the rectum and bladder, together with the extreme nature of the symptoms, gave weight to this view. This point being decided, the next question was as to the measure of relief proper in the case.

It was evident that it was not a dislocated kidney, but one congenitally displaced, for it could not be pushed from the iliac fossa. No apparatus nor operation looking to fixing the kidney in the lumbar region could therefore be entertained. In fact, the element of mobility held but a subordinate position in the matter of distress.

The question was thus narrowed to removal on the one hand, or bearing with the suffering on the other.

In view of the dangers of removal, the patient, at our suggestion, concluded to endure her distress as best she could, and left the hospital.

In a few days she returned, and said she had tried to work, but could not, and that, after consulting with her friends, she had concluded to submit to the operation. In looking over the subject, I found the most urgent matter to be determined was the condition of the kidneys.

Several cases had been reported in which, death occurring after extirpation, it was found that the remaining kidney was so far diseased as to be useless. There seemed no chance of this mishap here, as there was not, nor had there been at any time, evidence of kidney disease. During the menstrual disturbance there had been traces of albumin in the urine, but never casts nor renal epithelium, and in the intervals the urine was characteristically healthy. The final question was as to the absence of a kidney.

In view of the genital malformation, there was a possibility of but one kidney being present, but how to determine this was by no means easy.

The patient was placed in the knee-chest position, and careful percussion of the renal regions was made, the result being that there was dullness on the right side, and deep tympanic resonance on the left; the bimanual palpation of the lumbo-abdominal regions, owing to the tension and thickness of the abdominal walls, was negative. The method of Simon was now open to me (catheterization of the ureters), but the fact that, in common with many others here, I had tried this method several times, and had never succeeded (save when a large vesico-vaginal fistula existed), made me feel the attempt would be futile.

The method of examining the renal region by means of the hand in the rectum was discarded, for the reason that the pelvis was too small to permit of it without serious risk to the patient; it had been attempted while trying to determine the position of the uterus and ovaries.

The remaining method was the examination of the kidneys *in situ* after opening the abdominal cavity.

In planning the operation, my intention was to open the abdominal cavity in the median line as in ovariectomy, but, just before the day appointed, I saw a case of extirpation of the kidney in consultation, in which, after the operation, owing apparently to the action of the ligatures, dangerous obstruction of the bowels had supervened. This caused me to reconsider my operation. Referring now to the position of the tumor in my case, it will be remembered that it was situated in the iliac fossa, and that it could be easily pushed down as low as Poupart's ligament; it was evidently closely attached to the fossa, as was shown by the fact that with the patient in the knee-chest position it did not fall forward toward the abdominal wall; it was probably behind the peritonæum under the sigmoid flexure. Evidently it could be removed by an incision just above Poupart's ligament. If its position was as I supposed, I should not have to open the peritoneal cavity. I could secure free drainage from the end of the ureter and the vessels, along a short tract downward, with no possibility of coming in conflict with an important organ. These considerations prevailed, and I made my decision in favor of the incision just above Poupart's ligament. There were dangers either way, but I felt I had selected that along which the fewest lay. To save my patient from those that are common, that fill every operator's mind, when he goes through the peritoneal cavity and attempts to drain a possibly suppurating sac through it, I chose to assume the presence of two kidneys—to take the more remote risk of the patient having but the one kidney.

The patient being etherized, an incision was made paral-

lel to Poupart's ligament, about an inch from it; its upper limit was on a level with the anterior superior spinous process of the ilium, its lower just outside the internal inguinal ring. The sub-peritoneal space in the iliac fossa was speedily reached. Pressure from above brought the kidney into the opening; an incision was made into a dense layer of connective tissue surrounding it, and at once the organ came into view. It was easily enucleated, and removed. Two ligatures were used, one for the ureter and one for the artery and vein. No blood was lost. It was evident that I had not entered the peritoneal cavity; but, before I could close the wound, the patient showed signs of heart-failure. This, however, passed off under stimulation. The wound was closed to within half an inch of the lower angle, through which the ligature of the pedicle was brought out, and a piece of doubled drainage tube introduced. The principles of Listerism were carried out during the entire operation. It lasted twenty-five minutes. The further history of the case I now append, it having been prepared by Dr. Fruit-night, the House Physician.

In the subsequent history of the case the day is reckoned from midnight to midnight.

The temperatures were taken by the mouth hourly until November 7th; after that date every three hours.

In two hours after the operation, the patient had entirely rallied from the shock. As soon as she had been removed to her bed, she received 3 ss. of whisky hypodermically.

November 3d, 2 P. M.—In order to relieve her of considerable pain in the lower part of the back, she was given 10 m of Magendie, by the mouth.

3 P. M.—There being no subsidence in the pain, she received 10 m more, and in half an hour another 10 m.

4 P. M.—The dressing, having become displaced, was changed. The catheter drew off $\frac{3}{4}$ ij of urine, specific gravity 1.018; acid, $\frac{1}{2}$ albumin by volume.

6.30 P. M.—Vomited a little; her pulse is so small as to be scarcely perceptible; she is resting quietly, and complains now less of her back and more of her side. There is a slight oozing from the wound. She received Magendie 10 m, whisky 20 m, hypodermically.

7 P. M.—Vomited; pulse much stronger; catheter passed, no urine.

7.40 P. M.—Slightly chilly; vomited.

8 P. M.—Has been perspiring freely for the past two hours; received fluid extract of digitalis 5 m—not retained.

9.20 P. M.—Has had some sleep; still suffers from pain in the back and side; administered Magendie 5 m, hypodermically.

10 P. M.—Dressing changed; wound quite dry.

10.30 P. M.—Vomited.

12 midnight.—Slept quietly for an hour. Thus far the extremes of her temperature have been $98\frac{1}{4}^{\circ}$, at 2 P. M., and $99\frac{1}{4}^{\circ}$, at 9 P. M. Pulse ranged between 70 and 96; respiration between 36 and 12 (after Magendie). Taken and retained $\frac{7}{8}$ iv of milk.

November 4th.—To-day the patient vomited as many as eighteen times; the act was accomplished with considerable effort; it occurred more frequently, irrespective of nourish-

ment taken; the catheter was passed seven times, but no urine was drawn off.

The highest temperature point reached during the day was the highest in the course of the case, $101\frac{1}{2}^{\circ}$ at 7 P. M.; the lowest was 98° , at 10 A. M.

The pulse was unaltered in character, and also reached its maximum in the history, 132, at 5 P. M., the lowest register being at 1 P. M., viz., 80.

The respirations ranged between 13 and 26, irregular for a short time in the afternoon.

She slept quietly for about three hours. The pupils were evenly contracted, and remained so until the ante-mortem convulsion.

In the early morning complained of a pain in her side and back; relieved after hypodermic of Magendie, 10 m.

During the day she suffered from a hot, dry sensation in her mouth; relieved considerably by cracked ice and carbonic water *ad libitum*.

Tongue is quite clean.

1 P. M.—Digitalis poultices applied over kidneys; renewed hourly until the next day.

3.30 P. M.—The pulse is quite weak, and she appears to be faint. Whisky, 15 m hypodermically.

4 P. M.—Enema given; ineffectual.

4.45 P. M.—Pilocarpine hydrochlorate, $\frac{1}{4}$ grain, given hypodermically. In half an hour she broke out into profuse perspiration, that continued for perhaps one hour; during this time she was freely salivated; her pulse was unaltered in character.

7.50 P. M.—Dressing changed; wound doing well.

Pilocarpine, $\frac{1}{4}$ grain. Whisky, 20 m hypodermically; began to perspire in fifteen minutes, and continued slightly for an hour.

9.15 P. M.—Had a large, brown, watery movement. She received fluid extract of convallaria, 5 m.

11.15 P. M.—Pilocarpine, $\frac{1}{4}$ grain. Slight perspiration for half an hour.

11.45 P. M.—Fluid extract of convallaria, 5 m.

Before the use of the pilocarpine, the skin had been perfectly dry; afterward it was always more or less moist. During the day she took thirty-four ounces of milk; most of it retained.

November 5th.—Patient vomited seven times during the day. Catheter was passed 3ia qu. h., but no urine was obtained. Highest temperature, 101.2° , at 1 A. M. Lowest, 97.75° , at 9 A. M.

Pulse regular, 120° highest, several times during the twenty-four hours, and 88° at the lowest.

Respiration normal, ranging between 12 and 14.

The patient is not much changed in appearance; her face is still florid, with a slight bluish tinge under the eye. She expressed herself as feeling quite comfortable.

Once during the morning she complained of intense thirst; she slept about four hours at intervals; she had two small watery movements. Patient took and retained $\frac{5}{8}$ iv of milk.

The wound is healing kindly; there is no tenderness, tumefaction, or redness.

At 10 A. M. she became very much exhausted, was almost

pulseless, and her breathing was quite shallow; administered whisky, 3 1½, and tincture of digitalis, 5 m, hypodermically.

At 3 P. M. was given pilocarpine, ¼ grain, hypodermically. Whisky, 3 ½, per rectum, and placed in hot-air bath for half an hour. Profuse perspiration and expectoration set in, and lasted for about one hour. While in the bath, her pulse grew weak, there were twitchings of the fingers of both hands, and she complained of not being able to see plainly; gave whisky, 3 1½, hypodermically.

Fluid extract of convallaria, 5 m, was given twice during the day, and two more hypodermics of pilocarpine, one of ½ grain, and the other ¼ grain, were given, whisky, 3 1, being administered each time; each dose of pilocarpine was followed by profuse perspiration.

November 6th.—Vomited six times to-day. Catheter failed to obtain any urine. The temperature varied between 99.5° and 97.75°. (*Note.*—The temperature hereafter will not be noted, as it did not rise above normal.) Pulse varied between 88 and 120, which it registered once in the twenty-four hours; it retains its regular, small, and compressible character. The respirations ranged from 24 to 8 a minute, the latter being the lowest in the history of the case; at this time it was somewhat irregular in rhythm. She had considerable sleep in the twenty-four hours.

She lies quietly, talks intelligently, and suffers no pain. She received an enema, which was ineffectual. In the morning she was given a hypodermic of ¼ gr. pilocarpine, that was followed by profuse sweating for about three hours. In the afternoon, free perspiration set in, and continued for the rest of the day. She took 3 17 of milk, mostly retained, and 3 3 of whisky, in divided doses.

November 7th.—Vomited twelve times in the course of the day. Catheter was passed a number of times, but failed to draw off any urine. The pulse varied between 108 and 80, and was unaltered in character. The respiration ranged between 24 and 9 a minute. Perspiration was free, and the skin remained moist until 11 A. M., when it became very dry; a hot air-bath restored its action, and its activity continued the rest of the day. Several times slight jerking movements of the fingers and arms were noticed. A marked anæsthesia of the right lower extremity was noticed, that she had had for the last twenty-four hours; it has disappeared. She slept a good deal during the early part of the day.

Nourishment taken amounted to 3 17½ of milk. She was given 3 6 of whisky, in divided doses.

In the afternoon she was given two elaterium pills, ¼ gr., at an interval of three hours; the last one was not retained.

6.30 P. M.—Has had no movement in fifty-one hours. A large enema, containing 3 ½ of ox gall, was administered, and was followed by a full semi-fluid movement. Immediately afterward, she vomited with great effort; her face grew cyanosed, and there were decided convulsive movements of the upper and lower limbs for a few moments. She gradually became quiet, and apparently comfortable.

November 8th.—The pulse ranged between 108 and 80; it was regular, but generally quite thready.

Respiration ranged between 18 and 12. Before day-break she was very restless, and spoke at times in a disconnected manner. She complained of a severe back-ache, and numbness of the right hand. During the day she vomited frequently, a mouthful at a time. Her tongue is moist, and covered with a thin, white fur. She was constantly hawking and making efforts to clear her throat. As the morning advanced she grew more quiet, and her pain gradually disappeared.

By noon-time she seemed brighter than at any time subsequent to the operation, although her face was much thinner and her eyes were deeply set.

During the afternoon she suffered from an intolerable vesical irritation, and constantly begged to have the catheter passed.

Toward evening she began to talk wildly, but would stop when spoken to.

She takes short naps, waking with a start and scream.

At 6 P. M. she had an attack of vertigo; the rest of the day was passed quietly, and she enjoyed several hours of quiet sleep.

During the night she received an ox-gall enema, which was followed by a large, semi-fluid movement.

The wound was dressed once, and found doing nicely.

During the twenty-four hours she took 3 11 of milk; most of it retained. In the way of treatment she received digitalin, ⅛ grain, by mouth, at 4.30 P. M., 8 P. M., and at midnight. The event of the day was the withdrawal from the bladder of 3 2 of fluid—3 1 at 1 P. M., and 3 ½ at 3, and 8 respectively; its color was cloudy amber; on standing, several broad, white flakes were precipitated, its reaction was alkaline, and it contained a few epithelial bladder-scales, and a few red and white corpuscles. Upon chemical analysis, it was found to contain a very appreciable amount of urea; boiling completely solidified it; it had a slight urinous odor, similar to the perspiration.

November 9th.—Pulse varied between 100 and 80; weaker, but regular.

Respiration ranged between 12 and 16.

The fluid withdrawn from the bladder amounted to 3 9; its character was the same as the preceding. She vomited but four times; skin was moist all day, and at times she was perspiring freely; she had several quiet sleeps.

Twice during the day she complained of dimness of vision. At one time she was slightly delirious; now and then she is affected by sudden starts and twitchings of her hands; she has not lost much strength, tossing about constantly; she had one large loose movement.

The derangement of the dressing of the wound necessitated its renewal twice; it continues to do well.

She took 3 23 of milk; nearly all retained.

Treatment: She received five doses of digitalin (⅛ grain) during the twenty-four hours; 3 comp. cathart. pills at 3 P. M.

November 10th.—The extremes of the pulse were 104 and 80; at intervals it was weak and irregular in both force and rhythm.

Respiration ranged between 12 and 24.

Fluid obtained from the bladder amounted to 3 6.

She is less restless to-day, and obtained more sleep. She vomited twice, each time a very small quantity.

She had three large watery movements.

The patient does not appear to be much exhausted; her voice is strong, and she moves about without efforts; her features are, however, very much altered; the outlines of her face are more sharply drawn, her color is deeper, and her eyes are deeply sunken; she has occasional jerking movements and obscurity of vision.

The wound was dressed and the sutures were removed; union was found perfect; there is a slight healthy discharge from the lower part.

She received $\frac{3}{4}$ of milk, all of it retained.

Treatment: Digitalin, $\frac{1}{16}$ of a grain, at 3 and 7.30 A. M. Cupped twice over the kidney. Infusion of digitalis, 13, 9.1 h., from 7 to 11 P. M.; all retained.

November 11th.—The pulse ranged between 96 and 80, strong and regular the early part of the day, weaker later on; respiration varied between 18 and 12; the amount of fluid obtained from the bladder amounted to 33; she perspires a good deal, the skin being always moist and warm.

She feels weak, and complains of pricking sensations over the entire body. The twitching and dimness of vision continue; she had a short attack of hiccoughing; much of her time is passed in sleeping; the wound was dressed twice, and continues to do nicely.

She received $\frac{3}{4}$ of milk, none of which was rejected.

Treatment: From 1 A. M. to 9 A. M. she took $\frac{3}{4}$ of infusion digitalis hourly; at 7 A. M. she was so nauseated that her medicine was omitted.

November 12th.—Pulse varied from 76 to 96; it was weak, but regular. Respiration varied from 12 to 17. A few drops only of fluid were drawn from the bladder. She vomited three times. She lies in a semi-somnolent state most of the time, but is easily aroused.

She is almost constantly in a profuse perspiration. She had frequent attacks of hiccough during the day. The twitchings continue; dimness of vision not so much complained of; she has no pain anywhere. In the morning, a rose-colored eruption was observed on the arms and neck, slightly elevated, disappeared on pressure, and became more profuse and noticeable during the course of the day. She complains of the milk nauseating her; however, she took $\frac{3}{4}$ of it during the twenty-four hours, mostly retained.

At 4 P. M. she was covered with a cool perspiration, her face grew dark and purplish, and she complained of oppressive heat. Cyanosis grew more and more marked, breathing became difficult, and finally she went into a stupor that lasted until 5.30, when she gradually recovered and went to sleep.

At 9 P. M., complained of an annoying general pruritus. During the day she had six large, watery, offensive movements. Wound dressed twice; doing well. No medicines were exhibited.

November 13th.—Pulse varied between 96 and 80; is regular, but very weak. Respiration ranged between 12 and 15. Fluid drawn from the bladder during the day amounted to 3 iv. Patient has grown very much exhausted.

She lies quietly on her back all the time, and the eyes have closed. She wakes suddenly from her sleep, because of the violent convulsive movements of her arms.

These movements are present most of the time, but are more marked during sleep. She complained of intense itching several times, and had frequent attacks of hiccough; her mind is perfectly lucid. The eruption is quite profuse on the extremities and on the neck.

She refused her nourishment. $\frac{3}{4}$ ix were taken, and but little of it was rejected. She vomited four times, twice a greenish, glairy fluid, with considerable effort. Wound dressed twice; discharge slight. Treatment, none.

November 14th.—The pulse did not go above 84, and was regular. Respiration ranged from 16 to 12. Nothing was obtained from the bladder. Slept none at all to-day.

3 A. M.—Slightly delirious. Is unconscious of her surroundings. Imagines she is on fire.

8.15 A. M.—Her dressing changed; discharge slight in amount, offensive.

11 A. M.—Is resting easier, and appears more comfortable.

12 M.—Pulse 59. Small and irregular in volume and rhythm. Well-marked dyspnoea; eyes staring.

12.15 P. M.—Was having a general clonic convulsion, with the head rigidly turned to the right; fixed expression; staring eyes.

Subsequently, the body and extremities became rigid, and there were convulsive movements of the facial muscles, labored respiration, and widely dilated pupils. These active symptoms were prolonged about three minutes, and were followed by coma that lasted as much longer.

The respiratory movements gradually stopped, her heart ceasing to beat a short time before.

The duration of life after the operation was just eleven days and one hour.

The pathological report, by Dr. William H. Welch, is as follows:

Post-mortem Examination of a Young Woman, without Uterus or Vagina, and with only One Kidney, which had been extirpated.—The brain and spinal cord were not examined.

Exterior.—The body is well nourished. The chest presents typically feminine. There is considerable adipose tissue. There is no trace of oedema about the ankles or elsewhere. In the left iliac region, a little to the right of the anterior superior spinous process of the ilium, is an oblique linear incision 9 cm. in length. A drainage tube occupies the lower end of the wound. Above this the edges of the wound are carefully sutured and are firmly agglutinated. There is no unhealthy appearance about the wound. This incision leads into a cavity situated just outside of the peritonæum, from which cavity the kidney was removed during life.

Mammary Glands.—The mammae are large and contain much adipose tissue. Upon cutting through the glands, milk comes out in large quantity.

Peritonæum.—The peritonæum is thickened, somewhat glistening, and is free from all adhesions as well as from any evidences of acute inflammation. Even the peritonæum immediately adjacent to the cavity from which the kidney was removed presents a healthy appearance.

Heart.—The pericardial sac contains about two cubic centims. of clear serum. The heart is normal in size and appearance. Its

weight is 255 grammes. The left ventricle is firmly contracted and empty. The right ventricle contains a post-mortem white clot. The valves are delicate and entirely normal.

Aorta.—The caliber of the aorta is abnormally small. The diameter of the aorta ascendens is 18 mm.; that of the abdominal aorta just before the origin of the renal arteries is 9 mm. The wall of the aorta appears thin. The inner surface is free from atheroma or fatty degeneration.

Lungs.—Upon both sides there are old, firm pleuritic adhesions, most abundant upon the right side. There is no increased amount of fluid in the pleural cavities, and there are no signs of acute inflammation. With the exception of the old adhesions, the lungs are in all respects normal. Their parenchyma is reddish in color, elastic, dry, and crepitant. There is no oedema or congestion of the lungs. No mucus or pus can be squeezed from the bronchi.

Spleen.—The capsule of the spleen is somewhat thickened, and it is surrounded by old, firm adhesions which unite the organ to the diaphragm and the surrounding parts. The organ is enlarged, measuring 18 cm. in length. Its consistence is firm, its color reddish-brown, without trace of malarial pigmentation. The trabeculae show distinctly.

Liver.—The shape is that of a liver moderately deformed by tight lacing. The gall bladder protrudes; the left lobe is flattened, and is increased in lateral diameter. The consistence, the color, and the lobular markings of the liver appear normal.

Esophagus.—Normal.

Stomach.—The inner surface of the mucous membrane is reddened, and is coated with gray, thick, glairy mucus. The redness is due to hyperæmia, without noticeable ecchymoses. The changes are most marked in the pyloric region. The lesions are those of an acute catarrhal gastritis. There is no post-mortem softening or discoloration of the mucous membrane.

Intestine.—The mucous membrane, particularly that of the small intestine, is likewise reddened and coated with mucus in some places. In the large intestine are yellow fæces of soft consistence.

Pancreas.—Firm, and normal in appearance.

Supra-renal Capsules.—Both capsules are present, the right in its normal position, the left somewhat higher than normal. Their structure appears normal.

Kidneys.—Both kidneys are absent. There is no trace whatever either of the right kidney or of the right ureter. The left kidney was removed during life. It did not occupy its normal position, but lay in a space in front of the iliacus muscle behind and to the side of the peritonæum. This space which contained the kidney extends from a little above the crest of the ilium to the brim of the true pelvis. The sides of this space are composed of fibrous tissue, and present, over a considerable extent, granulation tissue. The external incision mentioned above leads into this cavity. Ligatures securing the left ureter and the renal arteries are attached to the inner wall of this cavity and project externally from the wound. There are two left renal arteries, measuring 6 cm. in length, given off from the aorta a short distance above its bifurcation. No renal artery is given off on the right side.

Ureter.—As already mentioned, the entire right ureter is absent. The left ureter pursues a nearly normal course from the point of ligation mentioned above to the bladder. The length of this portion of the ureter is 13 cm. The diameter of the ureter is 9 mm., being about twice the normal size. This increased caliber of the ureter is not due to any obstruction in the urinary passages. There is no trace of a second ureter belonging to the left kidney.

Bladder.—The bladder is contracted, and lies in its normal position behind the symphysis pubis. It measures, from vertex

to fundus, 7 cm. It contains a few drops of an opaque seropurulent fluid, but no urine. The mucous membrane is reddened from hyperæmia and from ecchymosis. It presents many distinct folds. The submucous tissue is œdematous. The lesions are those of an acute catarrhal cystitis. The opening of the left ureter is large and patent. The usual distinct fold (plica ureterica) extends from this opening along the left side of the trigonum vesicæ toward the urethral orifice. On the right side there is no corresponding fold, or plica, and no trace of the orifice of a ureter. Thus, in this case, the trigonum does not exist.

Urethra.—The urethra is 30 mm. in length, and normal in appearance. The external orifice is wide, and presents on each side a projecting fold of mucous membrane.

Vulva.—The labia majora have about the usual appearance and development. The labia minora, on the other hand, are very rudimentary, and are represented only by slightly projecting folds of mucous membrane. The clitoris is apparently absent, but above the urethral orifice is a recess surrounded by little folds resembling the præputium clitoridis.

At the situation for the vaginal orifice is an irregular opening, 3 cm. in length, which leads into a blind recess, or cul-de-sac, 2 cm. in depth. This orifice and recess were made by a surgical operation during life.

The perinæum measures 3 cm. in length.

Vagina and uterus are both absent. The peritonæum passes from the posterior wall of the bladder to the anterior wall of the rectum in the same manner as in the male. The floor of the recto-vesical fossa is smooth, and without any thickening.

Ovaries.—Two large and healthy ovaries are present in abnormal situation. The ovary upon each side lies upon the peritonæum covering the iliacus muscle external to the psoas magnus. *The left ovary lay directly over the left kidney before this was removed, and was separated from it only by the peritonæum and subperitoneal connective tissue.* The right ovary measures $6\frac{1}{2}$ cm. in length, 18 mm. in breadth, and 9 mm. in thickness. The left ovary measures $6\frac{1}{2}$ cm. in length, 20 mm. in breadth, and 13 mm. in thickness. Although the ovaries are somewhat larger than normal, they appear normal in structure. Their surface presents many cicatrices of ruptured Graafian follicles, and here and there can be seen little vesicles, which are ripe, or nearly ripe, Graafian follicles. Each ovary is closely attached along its whole length to the peritonæum. The usual white line (of Waldeyer) at the peritoneal attachment of the ovary can be seen.

Fallopian Tubes and Parovaria.—Upon each side are rudiments of the Fallopian tubes. Upon the right side the portion of the tube which is present measures $3\frac{1}{2}$ cm. in length. It presents a normal fimbriated extremity. The other extremity is rounded and closed. A probe can be passed into the tube up to this extremity. The diameter does not vary materially from that of the abdominal portion of the tube normally. This rudimentary tube lies near the ovary, to the base of which it is attached by a meso-salpinx, $3\frac{1}{2}$ cm. long and 3 cm. wide. This meso-salpinx is a thin and delicate membrane, in which can be seen distinctly the parovarium, measuring 20 mm. in diameter, and presenting its usual appearance. A single cyst, of about the size of a pea, with clear contents, lies in the folds of the meso-salpinx, immediately beneath the fimbriated extremity of the tube. Upon the left side only the fimbriae of the tube are present. A nodule of adipose tissue, about 8 mm. in diameter, lies between these fimbriae and the ovary, so as to obscure any evidence of a meso-salpinx or a parovarium if these structures existed.

Ovarian Ligaments and Round Ligaments.—The round ligament is represented upon each side by a firm, impervious cord, 13 mm. in greatest diameter, which can be traced from the ingui-

mal canal into the pelvic cavity, where it is lost in the subperitoneal tissue. *The left round ligament is lost in this tissue, corresponding to the posterior part of the lower portion of the bladder. The right round ligament can not be followed so far down into the pelvic cavity.* The left round ligament measures 15 cm., and the right one 10 cm. in length. Each round ligament is joined by the corresponding ovarian ligament, which passes from the anterior extremity of the ovary forward and somewhat downward. The ovarian ligaments appear as firm, fibrous cords. The right ovarian ligament joins the corresponding round ligament in the inguinal canal. The left ovarian ligament unites with the left round ligament a short distance above the brim of the true pelvic cavity. The right ligament measures 6 cm., the left 5 cm. in length.

The microscopical examination of the round ligament shows that it is composed of fibrous tissue and smooth muscular tissue, with blood-vessels.

Examination of the Kidney removed during Life.—With the exception of increase in size, the kidney appears normal. The length of the kidney is 13 centimetres, the width 7 centimetres, and the weight 198 grammes. The capsule is stripped off readily, leaving a smooth surface. Upon section, the cortex is of reddish-gray color. Its strim are distinct, and of normal appearance. The thickness of the cortex over the base of the pyramids is 16 mm. The pyramids likewise appear normal. Portions of the kidney were examined, both fresh and after hardening in alcohol, and showed no evidences of disease. There are no shrunken glomeruli, no thickened capsules, no increased intertubular tissue, no fatty degeneration of the epithelium.

A number of measurements were made of the diameters of the glomeruli and of the convoluted tubes (after hardening in alcohol).

The maximum diameter of the glomeruli is found to be 288 μ ; the minimum, 200 μ ; the average diameter, 235 μ .

The maximum diameter of the convoluted tubes is 98 μ ; the minimum diameter, 45 μ ; the average diameter, 64 μ .

Krause gives the diameter of the normal glomeruli as 200 μ to 220 μ , that of the convoluted tubes as 20 μ to 60 μ , average, 50 μ . Leichtenstern gives the maximum diameter of the normal glomeruli as 205 μ , the minimum diameter as 180 μ ; the maximum diameter of the convoluted tubes as 79 μ , the minimum 49 μ , average 62.7 μ .

In the present case the average diameters both of the glomeruli and of the tubes are somewhat greater than normal, so that these parts seem to be somewhat hypertrophied. This increase in the diameter of the glomeruli and of the tubes is, however, far less than that found by Leichtenstern in his case,* and is not so far beyond the normal limits as to justify any very positive conclusions in view of the wide variations in diameter to which the normal elements of the kidneys are subject. The measurements in this case favor the view that, with congenital deficiency of one kidney, the increased size of the single kidney is due mainly to hyperplasia. The moderate hypertrophy in the present case alone would not explain the increased size of the organ.

WILLIAM H. WETCH.

In concluding this article, I will make bold to offer a suggestion as to a method of procedure that may be used as a means of establishing the presence of two kidneys; it may also be utilized to determine the condition of the kidney that is to remain, in a case in which it is advisable to remove one because of its diseased state.

* Leichtenstern, "Ueber Nierenhypertrophie," Berlin. klin. Wochenschrift, 1881, Nos. 34 and 35.

Various methods have from time to time been suggested.

1. Catheterization of the ureters, a procedure very difficult to accomplish.

2. Exploration of the renal regions by means of a hand carried into the rectum, a measure difficult of accomplishment and not free from danger, giving you information, perhaps, as to the presence or absence of a kidney, but affording little or no evidence of its condition.

3. Cutting down upon the ureter of the kidney to be extirpated, as in the operation for tying the common iliac, passing around it a temporary ligature. Then washing out the bladder, collecting the urine from the kidney it is proposed to leave, and examining it—a certain but too serious a method.

4. The examination of the renal regions after opening the abdomen. This is a method that will determine the presence or absence of a kidney, but it will not afford sufficient proof of the integrity of the organ.

To overcome this difficulty, Glück has recommended the ligating or clamping of the ureter, the subcutaneous injection of a solution of iodide of potassium, then the examination of the urine a few minutes after for iodine. This method, although certain, exposes the patient to the dangers of abdominal section before the diagnosis can be made.

5. It has been suggested to compress the ureter of the kidney to be extirpated, at its crossing of the common iliac on the left side, or its crossing of the external iliac on the right side, by means of the hand in the rectum, or by a rounded wooden bulb. The bladder is first washed out, so as to get rid of all urine from the kidney to be extirpated. That which comes in must be from the kidney to be left. A chemical analysis being made of it, you have the best possible evidence of the state of the organ from which it has come.

6. The method I have to suggest is a modification of the latter. It is to compress the ureter at a point lower down. I confess it is easier of performance in the female than in the male, but I believe it can be accomplished in both. Take a large catheter, made of some substance like block tin, bend it to the shape of a Sims's sigmoid catheter; let the curve that passes into the bladder be as decided as it can be made, and yet not so great as to interfere with the ready passage of the instrument into the bladder. Suppose it to be the right ureter you desire to close. Introduce the instrument; then place the patient in the lithotomy position. Now carry two fingers as far into the rectum as possible.* Now place the catheter so that its curve in the bladder hugs the right pelvic wall; the end of the curve will pass directly across the line of the right ureter. Now press the fingers against the catheter, and the ureter will be sufficiently occluded to prevent all escape of urine. By means of the catheter in position (it may be double) you thoroughly cleanse and empty the bladder. As fresh urine flows in from the other ureter, it can be withdrawn and tested. As urine from a sound kidney is secreted at about the rate of a minim in four or five seconds, it will not require long-continued pressure to secure the amount of urine necessary

* An instrument of this shape may be made of any material, and be substituted for the fingers for occluding the ureter.

for satisfactory examination. In the female the procedure is more certain of accomplishment than in the male, because we can, in a measure, fix the base of the bladder by traction upon the anterior vaginal wall by means of a tenaculum hooked into it just below the cervix, or, better, well to the right of the cervix, on the lateral wall, the traction being downward and to the patient's left.

The fact that a patient can live, and be in fair condition, eleven days without any kidney tissue, would seem to prove that, if we can demonstrate the presence of a sound kidney, the removal of its diseased fellow (the disease reacting unfavorably on health and life) is not only permissible, but imperative.

NEPHRECTOMY FOR CHRONIC PYELITIS WITH LARGE PHOSPHATIC RENAL CALCULUS.

By J. WILLISTON WRIGHT, M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY
OF THE CITY OF NEW YORK; VISITING SURGEON TO BELLEVUE HOSPITAL, ETC.

Mrs. C., American, aged thirty-four, married, the mother of two children, the eldest aged thirteen and the youngest nine years. Family history good. Patient has always enjoyed fair health until about thirteen years ago, or since her first confinement. At that time she sustained a double laceration of the cervix uteri, which, in connection with sub-involution of the perineum, has occasioned more or less proctoidia, both of the uterus and of the bladder. During this time she has lost considerable flesh, has become thoroughly anæmic, has suffered much from frequent, severe, and protracted headache, from general debility, loss of appetite, constipation, inability to sleep, etc.

To these symptoms has been added, since the birth of her youngest child or for the past nine years, constant, dull pain in the right lumbar region, in the right loin, and frequently in the whole length of the spinal column.

About four years ago she first called my attention to the condition of her urine, which, on examination, gave the following results: Amount for twenty-four hours, variable (16 to 30 ounces); general appearance, pale, turbid; deposits, on standing, nearly one half of its bulk of a thick white sediment; odor, ammoniacal, fetid; reaction, alkaline; specific gravity, 1.022.

Microscopical Examination.—Pus corpuscles in abundance; blood-cells in moderate quantity; mucus; *débris*; bladder and vaginal epithelium, moderate amount. Crystals, triple phosphates; stars and rods of phosphate of lime or stellar phosphates.

In this connection, I may add that, after making a large number of careful microscopical examinations of the secretion, I was unable to find a single cast, and in only one sample was there found any of the peculiar epithelium of the kidney or of its pelvis.

The urine was at all times albuminous, but it was thought not more so than could be accounted for by the presence of a certain amount of pus and blood.

The feet and ankles were occasionally swollen at night; but, as the œdema usually subsided during the hours of re-

cumbency, it was regarded as passive in its nature rather than of renal origin.

With the impression, therefore, that she had no serious renal disease, and believing that many of her symptoms, including the ammoniacal state of the urine, might justly be ascribed to the condition of the uterus and perineum, and to their effects on the position of the bladder, I urged upon her the propriety of an operation for their relief, advice which had been given her two years before by Professor T. G. Thomas, who kindly saw her in consultation.

Accordingly, in February, 1882, I closed the laceration in the cervix with six carbolyzed catgut sutures, and the perineum with silver wire. At the end of ten days union of both wounds was complete, and the local result eminently satisfactory.

In the mean time, or during the two weeks of confinement to the bed, there was a marked improvement in the general appearance of the urine, consisting in a largely diminished amount of pus, blood, etc., rather going to confirm the somewhat vague suspicion which I had always entertained, that the alkaline state of the urine was possibly due to imperfect evacuation of the bladder, followed by rapid ammoniacal decomposition of its contents, owing to the displacement of this organ, as indicated above.

In view of the subsequent history of the case, however, I am now of the opinion that the improvement in the urine at this time was due to the recumbent position of the body alone, and the consequent lessened irritation of the kidney, as will be more apparent in the sequel.

April 1, 1882.—The urine for some time past has assumed its former unhealthy characters, with the addition of a perceptibly gritty deposit of phosphate of lime, leading me to suspect the presence of a calculus either in the ureter or the kidney, repeated examinations of the bladder having failed to discover anything there. The patient suffers intolerably with pain in the back and loin of the right side, which is only partially or temporarily relieved by assuming the recumbent position.

A careful physical examination in the region of the kidney failed to discover anything but the ordinary area of dullness on percussion.

April 20th.—For the last three weeks the urine has contained larger quantities of pus, mingled with a considerable amount of blood, but with an entire absence of symptoms referable to the bladder. Patient was seen, in consultation, by Professor William H. Thomson, who agreed with me in the diagnosis of chronic pyelitis, probably depending upon the constantly alkaline state of the urine, with, possibly, the presence of a calculus either in the ureter or kidney.

Ordered small doses of camphorated tincture of opium in an infusion of buchu, together with such an amount of alcohol as she could bear, in the hope of rendering the secretion acid. This treatment, after a faithful trial, had no other effect than to enable the patient to sleep somewhat better than before.

May 16th.—In order to determine if possible the question of stone in the kidney, a fine aspirator needle was passed through the lumbar region into the organ in various directions, being careful to avoid its pelvis and the close prox-

imity to it of the abdominal aorta and the ascending vena cava.

The result of the operation was purely negative, except that, in examining the bloody serum withdrawn by the aspirator, I found a single cluster of triple phosphate crystals—showing that the phosphatic condition of the urine was present even here, and did not, therefore, take place altogether in the bladder as a result of decomposition.

Another careful physical examination failed to make out the kidney, except as indicated by percussion.

June 1st.—Condition of patient unchanged, except that she is gradually losing ground.

Her treatment consists of tonics, mineral acids, with wine or punch, and as much nourishment as she can take, and which, on account of the irritable state of the stomach, often amounts to very little.

July 15th.—Condition unchanged. Another examination made with reference to feeling the kidney and, if possible, determining its size and general condition; negative, as before. Patient went to the country, but was so wretched while there that she returned at the end of two weeks.

September 22d.—During my absence from the city since last report, patient had occasion to consult my friend Dr. E. L. Partridge, who, in examining the abdomen with reference to some uterine displacement, discovered a tumor in the right loin. The tumor was now easily recognized by the touch, occupied a position between the lower border of the ribs and the crest of the ilium, was as large as the fist, very hard, quite movable, and very sensitive to pressure.

At about the center of its inner margin there was felt a nodulated mass, about the size of an English walnut, which was much harder than the remainder of the tumor, and which was much more sensitive, the patient complaining of nausea and great pain when it was handled, and especially when it was compressed between the fingers.

Believing the tumor to be the displaced kidney, and the nodulated mass a stone in its pelvis, I again made use of the aspirator needle, passing it through the tumor both from the lumbar region and from the loin in various directions, but without being able to encounter the calculus, probably from my great care in avoiding the large vessels in its neighborhood, as at the former attempt.

I now advised the removal of the whole kidney, after making a plain statement of the risks to be incurred, basing the advice upon the following conclusions, viz.:

First, the almost positive evidence of a large stone in its interior.

Secondly, the probability of the kidney being diseased and useless.

Thirdly, the fact of its being enlarged and displaced.

Fourthly, the strong probability of the patient's early demise from pain and exhaustion unless relieved by operation.

Fifthly, the facility with which the operation could be performed owing to the favorable position of the organ and the emaciated condition of the patient, together with the probabilities of the left kidney being sound, as indicated by the absence of casts in the urine, and in its ability to do the work of excretion alone, as it had doubtless been doing for several months, or possibly years past.

The patient cheerfully and gladly accepted the alternative, saying she preferred to take any risk which offered the faintest hope of relief, rather than to live on in her present condition.

Professors Thomas M. Markoe and T. G. Thomas were now asked to see the patient, confirm the diagnosis, and indorse the propriety of an operation. Both of these gentlemen agreed with me that the tumor in the loin was a displaced kidney, and, while not entirely unanimous as to the probable nature of its disease, were decidedly of the opinion, in view of the history of the case, that an operation for its removal would be eminently justifiable and proper.

Accordingly, at 3 P. M., October 14, 1882, in the presence of Drs. Post, Markoe, Polk, Iusk, Keyes, L. A. Stimson, Partridge, Wynkoop, Heuel, S. W. Smith, and Gibbs, the patient was brought under the influence of sulphuric ether, and an incision six inches in length made along the outer border of the rectus muscle on the right side, dividing the skin and superficial fascia down to the external oblique muscle of the abdomen. The other layers of the abdominal wall were then divided separately on a director down to the peritonæum. A few fibers of the attachment of the rectus to the seventh rib were also divided in order to obtain more room.

After controlling all hæmorrhage by torsion or the ligature, the peritonæum was incised on the director to the full extent of the wound. The right lobe of the liver now came prominently into view, projecting nearly two inches below the free border of the ribs, beneath which the kidney could easily be made out.

I next introduced my right hand into the abdomen, searched for, found, and examined the left kidney, making sure that it contained no calculus; that it occupied its normal position, and was of normal size and shape. The ovaries, uterus, and bladder, together with nearly all of the other treasures of the abdominal cavity, were interrogated in like manner, and were regarded as healthy.

The ascending colon was now drawn toward the median line of the body; the outer layer of the meso-colon scratched through with the blunt point of a director and the finger nail. On reaching the kidney, it was found to be somewhat adherent to the under or posterior surface of this layer of the peritonæum, as also to condensed bands of connective tissue in all directions. These, however, were separated by the finger without difficulty, and the kidney easily brought to the surface of the wound. The ureter was now tied with a strong ligature of carbolized, braided silk, and divided.

The four branches of the renal artery, together with the renal vein, imbedded in a mass of adipose and connective tissue, were secured on meso-ureter with catgut thread, and, of the same material, the kidney removed, and the ends of the ligatures brought out at the most dependent part of the wound.

The peritoneal cavity was then sponged out with a weak solution (one per cent.) of carbolic acid, and the wound closed with three deep silver-wire sutures, including the peritonæum, three hare-lip pins and three or four superficial silk sutures, supported by strips of rubber plaster, the wound covered with a thick layer of carbolized cotton, a firm ab-

dominal bandage, and the patient placed in a warm bed. The operation occupied one hour, a large portion of which time was consumed in making the external incision and in controlling all bleeding vessels before opening the peritonæum. The patient bore the operation remarkably well. There was slight failure of the pulse when the abdominal cavity was opened, but it soon rallied under the effect of one or two hypodermic injections of brandy, the last of which was combined with $\mathfrak{m}\mathfrak{v}$ of Magendie's solution of morphine.

At 8 P. M., pulse 80, of good quality, temperature 99.75°, respiration 20; slight nausea from ether. Ordered pounded ice to be swallowed frequently, and gave $\mathfrak{m}\mathfrak{v}$ of Magendie's solution of morphine hypodermically.

The kidney weighed $\frac{2}{3}$ vij, 3 v, grs. xxxv, was in a condition of chronic pyelitis. In its interior, and projecting into its pelvis, was an irregular, hatchet-shaped phosphatic stone weighing 135 grains. That portion of the stone which represented the blade of the hatchet occupied and distended the pelvis, while the part corresponding to the handle lay along the floor of the sinus.

October 15th to 20th.—Since the operation, patient's condition has been uniformly favorable. The pulse has averaged about 82 per minute, the temperature 100.5°, respiration 20. She has passed about twenty-six ounces of urine per day, presenting the following conditions: Reaction, acid; specific gravity, 1.016; albumin, none; pus, none; blood, none; crystals, none. The wound has healed by the first intention, except where the ligatures lead out.

October 20th.—Bowels have not moved since the operation. At 2 P. M., patient is very nervous, and complains of intense nausea; abdomen slightly tympanitic, but not tender. Ordered large turpentine enema, which relieved her of some flatus, but no fecal matter.

October 21st, 9 A. M.—Looks badly; has not slept during the night; very sick at the stomach; retching incessantly; complains of dyspnoea, due, evidently, to interference with the function of the diaphragm from the now greatly distended abdomen; pulse 90, temperature 99.5°. The turpentine enema was repeated, but it came away without even a change of color. Ordered cathartic of senna, manna, and Rochelle salts, after giving $\mathfrak{m}\mathfrak{x}$ of Magendie's solution of morphine hypodermically. This was promptly rejected.

October 22d, 5 A. M.—Has passed a bad night; there are now all of the evidences of intestinal obstruction. Ordered Magendie's solution, $\mathfrak{m}\mathfrak{x}$, followed by hydrarg. chlorate, gr. xx; 12 M., the calomel has been vomited, and the bowels have not moved; 4 P. M., large enema of carbonic-acid water, which came away unchanged; 6 P. M., Professor William M. Polk saw her in consultation, and regarded the symptoms as evidently those of obstruction without peritonitis; 7 P. M., passed rectal tube twenty-four inches into large intestine and injected through it two quarts of warm soapsuds containing a little turpentine, which brought away a small amount of liquid feces; 7.30 P. M., repeated the injection, with like result; 8 P. M., injected two quarts of carbonic-acid water, which, like the other injections, came away without affording any relief to the symptoms.

I now punctured the distended intestines through the abdominal walls in six or eight places with a small aspirator

needle, allowing the accumulated gas to escape; but as the vomiting continued, and believing that I had to deal either with an intussusception or with a twist in some portion of the small intestine, and as I felt sure the patient must die of exhaustion before midnight unless relieved, I resolved to open the abdominal cavity at the site of the original wound, introduce my hand, find the obstruction, and, if possible, reduce it.

The old scar was, therefore, divided with scissors to the extent of four inches, beginning at its lower extremity and using the ligatures, which still led out at this point, as a guide.

Having reached, in this way, the stump of the renal vessels and the ureter, I encountered, on their inner aspect, or toward the median line, a fluctuating tumor of the size of a hen's egg, into which I pushed a director, following this with my finger, and effected a free opening, from which about three ounces of very fetid pus were discharged.

The discovery of this abscess was something of a revelation, as there had been no symptom pointing to its formation, either in the way of pain, tenderness, rise of temperature, increase of pulse, or enlargement of that side.

As soon as the abscess was emptied, the ascending colon, which had evidently been obstructed at that point, as well as the other divisions of the large intestine, began a series of writhing movements, which could be seen plainly through the abdominal walls, accompanied by loud gurgling sounds, as of gas rapidly changing its locality. A considerable quantity of gas now discharged from the anus. Within twenty minutes the patient ceased vomiting and said she felt much better. The abscess cavity was washed out with a weak solution of carbolic acid, a drainage tube introduced, a hypodermic injection of morphine administered, and the patient left to rest.

October 23d, 9 A. M.—Slept three or four hours during the night; stomach quiet; has taken a little milk and brandy, and has retained it. Gave large enema through rectal tube, which brought away some fecal matter and much wind; 4 P. M., has had three large fecal movements since last visit; is greatly relieved thereby, but is thoroughly exhausted.

October 30th.—Has been in a very weak state since last report, but otherwise comfortable; has taken small quantities of milk, brandy, and beef-tea. Ligation on ureter came away to-day. The bowels have moved regularly; the abdomen has remained soft and natural, and free from pain or tenderness.

November 1st.—Urine turbid and offensive; contains a quantity of pus, with some shreddy particles and small coagula; has the same odor as the pus from the abscess.

I infer that the tied ureter has ulcerated off without closing its canal, and is draining the abscess into the bladder, especially as the abscess has nearly ceased discharging externally. Ordered bladder washed out twice daily with carbolic solution of borax.

November 15th.—External wound has healed, except where ligation on vessels leads out.

November 25th.—Ligation on vessels came away to-day, bringing with it quite a large mass of decomposed fat, fibrous tissue, etc.

January 13, 1883.—Since last report patient has re-

mained in a feeble state, owing chiefly, as I judge, to prolonged suppuration from the cavity of the abscess, which still continues to drain itself into the bladder. She passes an average of about thirty ounces of urine a day, which, aside from the pus it contains, is of a normal quality. She sits up for a short time each day, has a good appetite, good digestion, and is now evidently improving. Indeed, so far as the operation and the ability of her remaining kidney to do the work of excretion are concerned, I think I may safely say that the patient has recovered.

The chief cause, then, of her protracted illness after the operation seems to have been entirely due to a serious accidental complication, which, with a larger experience in such cases, might be avoided.

Remarks.—The operation of nephrectomy, first practiced by Walcott in 1861, and eight years later by Simon, has been performed about one hundred and six times, in forty-eight of which the results are known to have been fatal. This showing, though not of the most encouraging character, is sufficiently favorable to justify the operation in cases of incurable affections of the kidney in which it can be determined beforehand both that a second kidney exists, and that it is sufficiently healthy to do the work of excretion alone.

The kidney may be reached by one of three different routes—viz., first, through the lumbar region; secondly, by laparotomy performed in the median line; and, thirdly, by what is known as Langenbuch's method, or an incision through the abdominal walls at the outer border of the rectus muscle.

Thus far the lumbar incision has given the largest number of recoveries; but the necessarily limited extent of the incision in this locality, unless increased by resection of a portion of the twelfth rib, the greater depth of the wound, and the difficulties in dealing with such possible complications as hemorrhage, adhesions, etc., together with the acknowledged greater danger of diffuse cellular inflammation, would seem to more than counterbalance the extra hazard of opening the peritoneum by abdominal section.

Langenbuch's incision, on the other hand, certainly enables the operator to expose the kidney with great facility, and to remove it in all cases if necessary, which can not be said of the lumbar incision.

Langenbuch's method also has this great advantage over section of the abdomen in the middle line: that there is much less trouble during the operation from protrusion of the intestines, and that the incision comes almost directly over the tract of the ascending colon, thus enabling the surgeon to reach the outer layer of the meso-colon, which contains very few vessels, simply by turning the large intestine toward the median line.

The proper management of the blood-vessels of the kidney and the ureter is a matter which larger experience alone can determine; but that upon the rightful decision of the question will often depend the success or failure of the operation, so far as the life of the patient is concerned, there can be no room for doubt.

Judging from my experience with a single case, if I were to do the operation again I should endeavor to isolate the four diverging branches of the renal artery, as well as the

renal vein, from the mass of fat and connective tissue surrounding them, and ligate each one separately, even at the expense of a little longer exposure of the peritoneum, rather than to tie them *en masse*, as was done in the present case; moreover, I would cut the ligatures short and leave them to take care of themselves, in the hope that they would either become absorbed or encysted, rather than to lead them out through the wound, thereby encouraging the formation of a suppurative tract.

To a neglect of these precautions I attribute the occurrence of the abscess which has delayed the recovery of my patient during the past three months.

With regard to the ureter, I believe that whenever pyelitis is present, and especially whenever a calculus exists, either in the sinus or in the pelvis, this tube is necessarily diseased, and that an attempt should always be made; therefore, to remove as much of it as possible by ligating its vesical extremity and bringing the remainder of it out through the lowest part of the wound, as recommended by Mr. Thornton; another argument, by the way, in favor of laparotomy over the lumbar incision.

Had this been done in the present case, I have no doubt that my patient would have been spared the annoyance of having an abdominal abscess drain itself into her bladder, although, under the circumstances, it could hardly have selected a safer place, aside from the external wound.

53 WEST 130th STREET.

REMOVAL OF A VESICAL CALCULUS WEIGHING THREE THOUSAND FIVE HUNDRED AND FORTY-ONE GRAINS FROM A BOY SIXTEEN YEARS OF AGE.

By JOSEPH W. HOWE, M.D.,

PROFESSOR OF CLINICAL SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

THERE are many points of interest connected with the following case of urinary calculus. It is the largest calculus ever found in the bladder of a patient at so early an age as sixteen. Larger stones have occasionally been found in the adult bladder, before and after death, but they are of extreme rarity, and there are no cases that I can find on record of recovery taking place after their removal. The extraction of large calculi has always been attended with great mortality. The tables given by Crosse, in an analysis of seven hundred and four cases, afford a very clear illustration of this fact. He found that when the stone weighed from two to three ounces, the proportion of deaths was 1 in 2.18; from three to four ounces, 1 in 1.57; and from four to five ounces (the largest found), 1 in 1.66. In view of these statements, the successful removal of a calculus weighing over eight ounces, *avoidsupois*, must be regarded as exceptional.

The history of the case is as follows: Patrick Colbert, aged sixteen, residing at Greenpoint, L. I., presented himself at my college clinic, in Bellevue Hospital Medical College, on October 23d. He complained of pain in the region of the bladder during the act of urination, pain in the loins, and on the inner side of the thighs. There was a frequent desire to micturate, and a great increase in the pain during, and also after, the act. He first noticed pain during urina-

tion seven years before, but gave it little or no attention for a couple of years, until he noticed a great deal of sediment in the urine. He then consulted a physician in a city dispensary, who gave him medicine for what he called the gravel. The treatment relieved him for a while, but the painful symptoms returned again with renewed violence. Notwithstanding his illness, he was able to work at his trade in a junk-shop; but within the past twelve months he had frequent attacks of pain, accompanied with fever, compelling him to go to bed, where he would remain for several days, and then again resume work. An examination with a sound revealed the presence of a large stone. With the finger in the rectum its unusual dimensions were easily ascertained. Notwithstanding this, I deemed it advisable to attempt its extraction through the perineum, thinking that I might be able to crush it with a lithotrite. I was assisted during the operation by Professor Dennis, and by Drs. Schweig, Waldo, and Willis.

The patient was etherized, and a grooved staff was introduced and held in position by Professor Dennis. An incision was then made in the median line, an inch and a half in length, down to the urethra, which latter was opened almost to the same extent. Wood's bisector was then passed on the grooved staff into the bladder. The opening thus made admitted the index finger with great ease, when the size and general character of the stone were readily defined. Although convinced that it would be impossible to crush it or remove it through the perineum, I passed in Civiale's lithotrite, and endeavored to grasp the stone. Failing with this, I then tried Bigelow's instrument with a like result. Ceasing all efforts in this direction, the patient's position was changed and an incision three inches in length was made in the median line above the pubes, and continued down to the bladder. A sound introduced through the perineal wound into the bladder facilitated the incision through the anterior wall of the viscus, which was made from the border of the peritoneal fold above to the pubes below, fully exposing the stone. The bladder was then found to be firmly contracted on the stone in such a manner as to render it impossible to enter a forceps on its sides sufficiently far to grasp and extract it. After several vain attempts to remove it, both with the fingers and with the forceps, I passed my right index finger into the bladder through the perineal opening until it impinged on the lower border of the calculus, while above I grasped the rough projecting part with the fingers of my left hand. Then, by pushing with great force upward with the index finger and lifting with my left hand, I was enabled to force the calculus out of the bladder. It was held so firmly that several minutes were consumed in this manœuvre alone. During the manipulations through the abdominal incision the peritoneum was opened, and a loop of intestine came down. This was returned to, and retained in, its natural position without difficulty. The stone measured three inches in its longest diameter and two and a quarter inches in its transverse diameter. Its weight, as ascertained by Mr. Peabody, at Caswell, Hazard & Co.'s, was three thousand five hundred and forty-one grains.

After the removal of the stone, a piece of ice was placed

in the bladder, to control the hæmorrhage which took place from a spot on the floor of the organ, to which the stone

FIG. 1.

seemed to have been attached. As there appeared to be free drainage through the perineum, I concluded to follow the old rule, and not place any sutures in the walls of the

FIG. 2.

bladder. The opening in the walls of the abdomen was closed with silk sutures, excepting at its most depending

portion, where a space of half an inch was left for additional drainage.

The patient was ordered a teaspoonful of the United States solution of morphine, to be repeated every two or three hours until the respirations were down to thirteen a minute. In all operations where the peritoneal cavity has been opened, designedly or by accident, I have been in the habit of administering almost as much morphine as if the patient already had peritoneal inflammation. I am inclined to the opinion that peritonitis may often be averted by this treatment.

The patient recovered from the effects of the ether in a short time, but about an hour afterward began to show signs of collapse. His extremities became cold, and his pulse weak and fluttering. The house surgeon, Dr. Seabury, administered stimulants freely, and he soon rallied, seeming to be very little the worse for the operation. On the morning following, his temperature rose to 103° Fahr., and he complained of pain in his back, head, and limbs. The urine was oozing freely through the lower portion of the abdominal wound, and through the perineum. On the third day after the operation (Wednesday), the urine had ceased to flow through the perineal wound, owing to the inflammatory tumefaction there, but it escaped very freely through the lower part of the opening in the abdomen. A small quantity also came away through the urethra. In order to make the drainage perfect, another suture was removed in front, which left over an inch of the incision at its lower part open. This was necessary, in order to insure the absolute safety of the peritoneal cavity, which had been opened during the operation. His temperature at this time was 102° Fahr., pulse 98. A gum-elastic catheter was introduced through the perineum into the bladder, and allowed to remain. The following day, as only an ounce of urine had passed through the instrument, and as it occasioned considerable pain, it was removed, leaving the drainage to the abdominal opening. The urine flowed constantly at this point, and a few drops also escaped through the urethra. The temperature was down to 100° F., and his pulse ranged between 90 and 100. On Friday, the urine began to have an ammoniacal odor, and he complained of some pain in the hypogastric region. The bladder was then washed out with carbolic water, and afterward with a solution of borax. These washings were repeated three or four times daily until the opening got too small for the catheter.

On Saturday, his morphine was discontinued, with the result of bringing about a state of partial collapse. His temperature became sub-normal (97° F.), and his pulse was weak and thready. The renewed administration of the morphine, in conjunction with whisky and digitalis, soon relieved him. This sinking occurred again a few days afterward, from a similar cause, and was relieved, as before, by stimulants.

Little or no change occurred in his general condition during the next few days. He ate well, slept well, and had little or no pain. Two weeks from the date of the operation he was dressed and allowed to go up-stairs to the lecture-room of the college. He expressed himself as feeling strong and able to resume his work in the junk-shop. The

urine was still flowing freely through the abdominal wound, though the opening was comparatively small, and seemed to be closing rapidly. A small quantity of urine was passed by the urethra, but none whatever through the perineum. The daily washing of the bladder was discontinued about this time, owing to the pain produced at the narrow opening by the passage of the nozzle of the syringe, and also because the water was comparatively free from ammoniacal odor.

Four weeks from the date of the operation the abdominal wound had entirely healed, and all the water was passed by the natural channel. He left the hospital a few days later, entirely well.

An analysis of the stone was made by Professor Doremus. He found that it "consisted of a central mass of nuclei, and five surrounding layers. The nuclei consisted of oxalate of lime. The first layer of matrix, in which the nuclei are imbedded, is composed of phosphate of magnesium and ammonium, phosphate and carbonate of lime, and traces of oxalate of lime. The second layer of matrix consists of phosphate of magnesium and ammonium and phosphate of lime. The third and fourth layers have the same composition. The fifth layer is formed of large crystals of phosphate of magnesium and ammonium. The two inner layers are the most compact. They contain a greater proportion of the phosphate of lime than of phosphate of magnesium and ammonium. The center layers are full of little cavities, being the spaces between the crystals. The whole calculus is remarkably free from uric acid or the urates. Even the dust from all parts of the calculus, the result of cutting it in two, yields but the slightest reaction for uric acid."

From a careful study of this case, and from an examination of the records of the extraction of large calculi through the perineum and rectum, I am convinced that the suprapubic operation is the only safe one. The stone can be removed without lacerating important organs. Free drainage can be kept up through a perineal opening, as well as through the lower extremity of the abdominal incision, thus reducing to a minimum the danger arising from urinary infiltration and peritonitis.

A TRUSS FOR THE RETENTION OF FLOATING KIDNEY.

By A. A. SMITH, M.D.

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF CLINICAL MEDICINE, IN ILLINOIS HOSPITAL MEDICAL COLLEGE.

HAVING tried, in a case of floating kidney, to give relief by means of a compress and adhesive plaster as has been recommended, and failing, it occurred to me that a modification of a hernia truss might be of service. I described as nearly as I could to Mr. W. F. Peck what I wanted, and he constructed for me an instrument which resembled the hernia truss, except that the spring was straight instead of oblique. The posterior pad was oblong and was padded very little, the anterior one was round and padded quite full. The instrument answered the purpose fairly well. It kept the kidney from coming down and forward beyond the free

border of the ribs, and gave great relief to the unpleasant symptoms, but the patient complained of the pressure of both pads. She was quite nervous and hyperæsthetic, and was unable to wear it for more than a day or two at a time. The spring was purposely made long enough for the posterior pad to rest on the side of the spinal column, opposite to that on which the displacement occurred. About two years ago I showed the truss at a meeting of the Clinical Society, and asked for suggestions which might improve it. Dr. F. P. Foster suggested that if four small pads were placed at the posterior end of the truss it might be worn with more comfort. These pads were accordingly put on, so that two could rest on each side of the spinal column. This was

found to be a decided improvement. I had also a soft rubber air-pad put on anteriorly, and this has entirely overcome the objections to pressure, and makes it cleanly. The air-pad may be blown up, by a tube attached to it, and made very tense, or it may be made quite flat.

I have used the truss in two cases with very decided benefit. One of these patients was treated by different physicians for a long time for uterine and ovarian displacement, with no benefit. She now declares her symptoms, which have been attributed by her physicians to such displacements, are entirely relieved by the kidney-truss. She also makes the statement that she can now walk miles with comfort, whereas before she was not able to walk a few blocks without great discomfort.

In these cases the right kidney was the one displaced.

It is not expected of this truss that it will keep the kidney back in its proper place. All that can be hoped for from it is that it will prevent the kidney from wandering about the abdomen, coming in contact with other viscera, and preventing it from becoming twisted, which is probably the cause of the pain and great uneasiness so frequently complained of.

All patients with floating kidney will not consent to having it transfixed and stitched to the abdominal wall, as has been quite frequently done, nor will patients with a floating kidney which is otherwise perfectly normal always consent to have the kidney removed by abdominal section, as has been recommended and performed at least once in this country. This latter procedure I confess I am more than skeptical about. I am decidedly opposed to it, nor can its performance be justified on any other ground than that the affection makes the life of the patient miserable by the constitutional disturbance which it may produce. Even

under such circumstances it would be well to be thoroughly satisfied that the constitutional disturbances are due to the floating kidney.

I believe this truss will very frequently hold the kidney back from coming below the border of the ribs, and give decided relief.

Book Notices.

A Treatise on Therapeutics, comprising Materia Medica and Toxicology, with especial reference to the Application of the Physiological Action of Drugs to Clinical Medicine. By H. C. Wood, Jr., M. D., Professor of Materia Medica and Therapeutics, etc., in the University of Pennsylvania. Fourth edition, revised and enlarged. Philadelphia: J. B. Lippincott & Co., 1882. Pp. 736. [Price, cloth, \$6; sheep, \$6.50.]

In the very brief preface to this edition the author states that, "by a thorough revision of the book, with the aid of the most recent literature, he has endeavored to make it as perfect as he is able."

This statement, from such a source, is enough to assure the reader that he will find in the work the same thoroughness, and yet conciseness, which has marked the previous editions. The present book is larger by some dozen pages than the third edition. No essential changes appear, such additions as have been made being almost entirely under the sections devoted to the physiological action of drugs. The author does not abandon the wise conservatism which has distinguished his writings, or swell his list of remedies to suit the present rage for novelties. Turning over the pages, we note here and there a slight modification. The section on "Disinfectants" remains essentially the same, though we might have looked for some reference to the changes in pre-existing ideas as to their efficacy; that on "Emmenagogues" is as brief as before, in spite of the recent introduction of new remedies in that department. Under "Anæsthetics" we note a short paragraph on bromide of ethyl, its use being condemned. We might have expected some reference to the use of pilocarpine in diphtheria, of iodoform in surgery, of the new resins, such as resorcin; but, doubtless, the author decides, and wisely, to accept no new theories until they have been thoroughly proved. Wood's Therapeutics is not easy reading, neither can it be approached lightly, yet to the thoughtful reader it is pre-eminently a satisfactory book, appealing to his reason, while it stimulates his powers of observation. The student who has caught the spirit of its author can never become a mere routine therapist.

BOOKS AND PAMPHLETS RECEIVED.

The Annual Address, delivered before the American Academy of Medicine, at its Seventh Annual Meeting, in Philadelphia, October 26, 1882. By Traill Green, A. M., M. D., of Easton, Pa., President of the Academy. Philadelphia, 1883. Pp. 16.

Nineteenth Annual Report of the New York Society for the Relief of the Ruptured and Crippled, November, 1882. New York, 1882-'83. Pp. 32.

Scrofula and its Gland Diseases: an Introduction to the General Pathology of Scrofula, with an Account of the Histology, Diagnosis, and Treatment of its Glandular Affections. By Frederick Treves, F. R. C. S. Eng., Assistant Surgeon to, and Senior Demonstrator of Anatomy at, the London Hospital, etc. Philadelphia: Henry C. Lea's Son & Co., 1883. Pp. 77. [Paper; price, 10c.]

THE NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 17, 1883.

URINARY SURGERY.

It will be noticed that this number of the journal is largely devoted to the surgery of the kidney and bladder. Were it only for the mere fact of our giving two cases of an operation that is at the present time exciting so much interest as that for the removal of the kidney, we should feel gratified at being able to lay such material for comparison before our readers; but, when we reflect upon the extraordinary features that will be seen to have been present in these two cases, as well as in Dr. Howe's case of supra-pubic lithotomy, the surpassing interest of this group of articles becomes obvious.

In view of the boldness with which the operative surgery of the present day grapples with grave visceral disease, as exemplified by paracentesis of the pericardium, by the modern treatment of empyema, to say nothing of the idea of treating pulmonary cavities *per viam artificialem*, by cholecystotomy, by the removal of portions of the intestinal tract, of the spleen, of the kidney, of the ovary, and of the uterus—in view of all this, it seems only a question of time, and very little time at that, when the great operations, as they then seemed, that brought glory to former generations of surgeons shall be relegated to the domain of minor surgery, to be served up in manuals "designed for gentlemen preparing for examination." Some phases of this advance of operative surgery are more striking, more bloody, more brimming with the zest that springs from the appreciation of their being fraught with immediate peril; but that one of its aspects that unfolds to us the bold and steady push with which diseases of the urinary tract have been met reveals, equally with the former, the unmistakable features of grand surgery. Not only is this true of nephrotomy and nephrectomy, but the patient, careful, and multiplied achievements of Sir Henry Thompson and the brilliant conception and persistent work of Dr. Bigelow proclaim an amount of progress that goes far to place urinary surgery among the most advanced branches of our art.

While floating kidney is a condition that can scarcely be called a grave affliction, we are convinced that its importance is generally underrated. To what extent it may prove a burden to the individual, interfering with the pursuit of a livelihood, may be gathered from Dr. Weir's lecture. By improving palliative measures, as Dr. Smith has done, many a sufferer may doubtless be relieved. Still, in a certain contingent of cases, recourse must be had to an operative procedure. Wandering kidney, however, was not the condition that Dr. Polk had to deal with in the remarkable case that he relates in this number of the journal, but a misplaced kidney, giving rise to the most serious derangement of health and to a grave disability. As

comment founded on insufficient data in regard to this case has been given by some of our contemporaries, coupled with the suggestion that the unfortunate circumstance that the patient proved to have had but one kidney should act as a check upon the further performance of nephrectomy, we hold Dr. Polk's full and candid recital to be of the utmost importance. The risk he took was justifiable, but the worst that could have been anticipated unfortunately proved to be the case. This often happens in medicine, and must keep on happening so long as the art continues to fall short of perfection. The ingenious device of blocking up one ureter for the time being, by means of an instrument introduced into the bladder, so that the presence or absence of the other kidney may be ascertained, and, its presence having been determined, its probable capability of performing the work of two kidneys made out—a means that has occurred to Dr. Polk since his operation was performed—will doubtless meet with the attention that any measure having for its object the solution of such urgent questions ought to command. Actual trial must, of course, be made the final test, but *a priori*, while the manœuvre alluded to would undoubtedly call for a considerable degree of manipulative skill to make sure that it was adequately carried out, it may be looked upon as less objectionable than any proceeding heretofore devised for the purpose, if we take all sorts of cases into account.

Dr. Wright's successful case of nephrectomy is not only a striking example of what may sometimes be achieved, even under the most desperate circumstances, by a persistent employment of all possible resources, but an apt text for just such a discussion as Dr. Wright gives of the relative advantages of the lumbar and the abdominal incision.

The survival of the lad from whose bladder Dr. Howe removed so enormous a calculus by the high operation bears fresh testimony to the vigor of the recuperative powers in young persons with only local disease or injury. It illustrates also the wisdom of forbearing to persist in trying to drag a stone of such size through a perineal incision, and of resorting promptly to the more available region above the pubic arch. It may be doubted, indeed, if a preliminary perineal cystotomy, not altogether tentative in its purpose, might not often facilitate the removal of large calculi from the bladder by the supra-pubic operation, and add to the patient's chances of recovery.

LEPROSY IN THE UNITED STATES.

At a recent meeting of the New York Dermatological Society, the subject under consideration being a case of leprosy in the person of a patient that had been shown at the meeting, the question arose, how many cases of leprosy had been seen by the members who were present, not more than ten in number. These gentlemen, speaking from memory, and taking care to give such details as would prevent any one case from being counted twice, were able to enumerate about thirty leprosy patients that had come under their own observation in New York and its immediate vicinity within the last eight or ten years.

Various localities through the country were also mentioned,

in which, within the knowledge of those present, single lepers were living; allusion was made to the well-known prevalence of the disease in certain districts within the Dominion of Canada; and it was stated that in the far Northwest, in the region lying between Puget's Sound and the Columbia River, the affection was very common among the aborigines.

Leprosy is probably seldom thought of by the great mass of our people, save in connection with the allusions made to it in the Scriptures, and even then it is doubtful if they realize in the slightest degree that the leper of antiquity has his counterpart in many quarters of the modern world. As a matter of course, those who have traveled in China, Norway, Spain, the West Indies, and various other countries in which the disease is common, as well as a few students whose reading has made them familiar with its prevalence in those parts of the world, are fully aware that leprosy has by no means ceased its ravages. As regards the community at large, however, and even a great many physicians who are not specially conversant with the literature of the subject, we can scarcely suppose that they entertain the slightest idea of the importance of the matter.

When we remember that leprosy prevailed in Great Britain and other countries, now nearly or quite free from it, in comparatively recent times; when we take into account the considerable Scandinavian immigration to our shores now going on; and, above all, when we reflect that the policy of isolation pursued by communities in which the disease is rife is not an ostracism of the leper on account merely of his loathsomeness, but a wholesome precaution for the general safety, founded on the conviction that leprosy is contagious, which conviction is forcing itself more and more on those who have made the matter a subject of scientific study—when we take all these things into consideration, and couple them with the grim fact that leprosy leads infallibly to death within a few years, we may well ask if it is not desirable for us as a people, and if it is not incumbent on the Government, to take steps to prevent the spread of the disease in this country. To be sure, the contagiousness of leprosy is not the rank communicability of the acute infectious diseases, nor perhaps does it rank with syphilis in this respect; but that it is contagious to such a degree as to make it unsafe to allow its victims to go in and out among their fellow-men year after year, seems to admit of little if any question. Certainly, the community should give itself the benefit of whatever doubt there may be in the case, and isolate the leper ruthlessly, and, as regards leprosy immigrants, forbid their landing on our shores.

THE ELECTRICAL TREATMENT OF EXTRA-UTERINE PREGNANCY.

DR. A. D. ROCKWELL recently read a paper before the Harlem Medical Association, on the treatment of extra-uterine pregnancy, in which he referred to the first case which he was called upon to treat, a few years before, when the question was asked whether it was possible to destroy the life of the fetus by the electric current. He replied that it could undoubtedly be done, but another question was, whether it could be accomplished without injury to the mother. This question was answered in the affirmative by the results that followed. The case

was one of tubo-interstitial pregnancy at the third month, an account of which, written by the attending physician, Dr. Charles McBurney, appeared in this Journal (vol. xxii, No. 3). Three other cases successfully treated by Dr. Rockwell have also published, the diagnosis in every instance having been confirmed by Dr. Thomas, and, in most of them, by Dr. Emmet also. More lately he has treated three other cases which have never been published, and which, if possible, even more strongly confirm the incalculable value of the treatment in these dangerous but somewhat rare abnormalities of pregnancy.

One of these last three cases was of a most interesting and unusual character, from the fact that with a normal uterine pregnancy was associated what, in the opinion of Dr. Thomas, was a tubal or extra-uterine pregnancy. Internal examination and conjoined manipulation revealed a tumor of about the size of a pullet's egg, situated about two inches to the left of the median line, nearly on a level with the brim of the pelvis, which could be moved from Douglas's cul-de-sac toward the margin of the ribs. The tumor gradually increased until it was larger than a billiard-ball. In the treatment, one pole was introduced to the mass through the vagina, and the current was rapidly interrupted.

The maximum of current strength employed was eighteen cells, or, to speak more accurately, as different apparatus vary much in electro-motive force, a power of 24 volts. The operation was repeated on October 25-28, and 30, 1882, causing the tumor not only to decrease perceptibly in size, but to change its seat by an inch or so as well. Since the last application it has gradually grown smaller, until now it can barely be detected. At the same time a six months' fetus is now developing in the uterus.

In these conditions Dr. Rockwell decidedly prefers galvanism to other forms of electricity, both from the teachings of experience and because of the well-understood superiority of galvanism in physical, chemical, and physiological action. In any case of tubal pregnancy, and especially in those advanced conditions where the tube is greatly distended, and there is danger of spontaneous rupture, the possibility of hastening this catastrophe should never be lost sight of.

The tubes themselves are but slightly supplied with muscular fibre, and the danger would more especially arise from the powerful compression that is liable to be exerted by the abdominal muscles, and the effort should be so to diffuse the current proceeding from the external pole as to produce the least mechanical effect possible. The diagnosis of extra-uterine pregnancy is not always an easy matter, and in the various cases related the question might arise as to its accuracy. The eminence of the gentlemen associated in the cases, Dr. Rockwell thought, should be a sufficiently strong argument for the correctness of the diagnosis, but conclusive evidence, he thought, lay also in the effects of the treatment itself. The results of electrolysis are well known, but in no other form of tumor, cystic or otherwise, is it possible for the galvanic current, used as described, to produce such prompt results.

RARE DISLOCATIONS OF THE HUMERUS.

IN the "Nordiskt Medicinskt Arkiv" Dr. Leopold Meyer, of the Kommunehospitalet in Copenhagen, describes two cases of the "*luxatio humeri erecta*" of Middeldorff. In the first case, a woman, sixty-two years of age, fell in an epileptic convulsion eight days before her admission to the hospital. On regaining consciousness she became aware that her left shoulder had been injured, and the arm was fixed over her head. On entering the hospital she presented all the characteristic signs of a sub-glenoid luxation; but, besides a very pronounced abduction, the

arm was carried almost vertically upward, the forearm being flexed upon the arm so that the hand rested on the head. With the aid of anesthesia, reduction was accomplished readily, by abduction and extension, followed by adduction. A paralysis of the nerves of the brachial plexus remained, which was attributed to the length of time that had elapsed between the infliction of the injury and the reduction of the dislocation. It did not yield to electrical treatment. The second case was that of a man who presented precisely the same dislocation. Reduction was effected at once, and he left the hospital.

In the same article the author reports, also, the case of a woman who dislocated both humeri at the same time by a backward fall while she was carrying a burden with each hand. In this instance both luxations were of the sub-coracoid variety.

Proceedings of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DAY.—TUESDAY, FEBRUARY 6TH.

Evening Session.

(Concluded from page 162.)

[Dr. SQUIBB continued his remarks as follows:]

It may be said that this action was only concluded by the delegates who represented the county societies. But delegates with full power upon the general subjects of legislative bodies have no power to make constitutional amendments, and their action ought to be reversed. Nearly, if not quite, forty counties of the State have already condemned the action of this society, while the majority of the others have either not acted at all, or their action has not been published. Any revolutionary action should first be submitted to the American Medical Association before it is acted on by the State societies. In offering the resolutions, I only advocate the first. A year or two hence, action may become necessary on the others.

Dr. L. ELSBERG, of New York, moved that the Committee of the Whole report, when it rose, that the resolutions were not approved.

Dr. D. B. ST. J. ROOSA: The argument of the distinguished gentleman who has during the year inundated the State of New York with arguments against the society, merits, as it will receive, the most respectful consideration from those who can not agree with his conclusions. We honor him for a life devoted to the most sacred interests of the profession. We regret that he has given his great ability to the fossilism of the seventeenth century. The argument of the gentleman, if led to its logical conclusion, would disintegrate the society and blow it to the winds. The notion that these county societies may come up here and assert their right of secession would be regarded as absurd if it did not come from such distinguished lips. It is true that instructed delegates have come here from various societies, but there are other members here from the same counties, holding different views. Because New York happens to be large, is it to have no more votes than Alleghany County? If there ever was a spontaneous convention, it was the meeting of 1882. The action in adopting the new code was not taken in any packed convention of specialists. It was only equalled by this meeting here to-night. There was no unfair advantage of any kind, notwithstanding the assertions to the contrary. That meeting of the society did represent its constituents perfectly well. The discussion was an open discussion; the gentleman had his full say there. Mr. President, it is assumed by the gentleman that we have a connection with the American Medical Association. Let

us say, Mr. President, distinctly, we recognize no allegiance to the American Medical Association. The American Medical Association is not an incorporated association. It has never taken any position in the medical world that is at all to be compared with that of this society of which we have the honor to be members. The gentleman lays great stress on the word "revolutionary." All the advances in the world have been made by revolutions. Not against us can any such charge be made. The county of New York comes here unfettered and untied. The county of Kings is also unfettered, and almost united in upholding the action of the State society in 1882. The advancement of the profession would be promoted by resistance to the resolutions which are offered for the consideration of the society to-night. Gentlemen come up here bound and fettered as to what they shall do. When I had the honor to be president of this society, I instructed members that instructions of this kind were not binding.

If you are not willing to trust the ex-presidents of this society who favor this movement, whom will you trust?

It is said that this is a medical question. There I take issue at once. This is not a question of drugs or drugging; this is a question of ethics. All the community has been laughing at us for the last half-century. If we put upon our escutcheon that we seek to alleviate humanity, we shall be right, and we can afford to smile at those who uphold the trades-union system. The State Society should be liberal and progressive in its ideas.

Dr. H. G. PIFFARD: The gentleman undertook to show that our code of ethics was a sort of constitution; this, I think, is an error. The gentleman seemed to think that the county societies have the power to control the by-laws of this society. The gentleman overlooks the existence of the law of 1866, which gives to the State society control of the by-laws of the county medical societies. This is certainly the first time that I have ever heard the question raised of referring our by-laws back to the county societies. Let it be clear that the code is not analogous to the constitution of the State. It is simply a by-law which we can modify or repeal, and our action must be accepted by the county societies.

Dr. H. R. HOPKINS, of Buffalo: In the year 1806 there was a conviction in the minds of the people that it would be advantageous to organize the medical profession into societies, and this society was organized under an act passed that year. The scope of the society is defined within certain limits. Within these wide limits the society is supreme. We are assembled to-day from every part of the State, and we are to consider a question bearing upon the interest of the whole State. The essence of the question is, "Are we capable of self-government?" In the consideration of the question we now have before us, it is important that we should have clear ideas. The grant of the people to this society is the right to make by-laws "not contrary to, nor inconsistent with, the laws of the State or of the United States."

The first question is, Have you, Mr. President, the right to call upon others for their opinion? The next question is, Why have not I and others the same right? To maintain that one may refuse to consult with another because he does not like him is absurd. The practice under the old code may be fairly expressed by putting it in this way, "that no consultation shall be held with regularly licensed physicians who hold eclectic or homœopathic views." The people have created this society, and also eclectic and homœopathic societies. When this society assumes that its members may not meet regularly licensed physicians in consultation, it makes itself ridiculous.

Dr. H. D. DIDAMA, of Syracuse: I did not think it was quite so bad as the paper just read has put it. The two points I make are, first: This code of medical ethics, under which we have

been living and prospering, is one which we adopted as a condition of having representation in the American Medical Association. If we repudiate this code, then we have no right to representation in the American Medical Association. There is a little complaint to-day that our delegation was not received with respect and with open arms by the American Association. They were bound to refuse delegates who were sent from a society which repudiated their laws. There are three gentlemen here who are responsible for this code. Are we prepared to go with the fifty-three gentlemen who said last year that we should cut ourselves loose from the American Medical Association? The American Medical Association comprises in its membership the best men in the land. The best of us look up to the wise men there. We have been there as members, and we don't want to be cut off from them. I am in accord with the best societies throughout the world.

My other point is this, and this is a moral question—the first is a matter of taste; we could live, perhaps, if we were cut off from them: I take it that we all agree that a consultation is a conferring together. A consultation is a fraud, where no good can possibly come to the patient, when physicians consent to consult with persons who differ from them as light does from darkness. Those gentlemen who support the new code, will they tell me how any possible good can come to the patient by consulting with a man who believes that an ordinary dose—five grains of quinine—should be diluted in twenty-eight hogsheds of water, of which solution one drop should be given as a dose? Dr. Roosa knows that the homœopath would not give a dose containing any appreciable quantity of medicine. We claim that we give something, and they give practically nothing.

Dr. THOMAS F. ROCHESTER, of Buffalo: I rise with the full consciousness of the importance of this question. We have to look at the common sense of it. I say there is no casualty, there is no emergency, that medical men do not always go to, without regard to compensation. I am a permanent member of this society and of the American Medical Association, and I am proud of both of them; but, if I have to give up my membership in either, I will give up my membership in this. The American Association has been a called junketing association, a Rip Van Winkle association. What is this word "progress"? It is a good deal like the Irishman's definition of a retrograde movement—"an advance backward." What are we to gain by the first clause of this new code? It says we may go into consultation with homœopaths or others. Thus we have started down from our plane to meet them; they don't come up to meet us. What do we expect when we do go to them? We meet, we talk, we don't agree in therapeutics or diagnosis, but the people are satisfied. We can not do this without degrading ourselves, and I can not see any possible advantage to result. We can not reform homœopathy. But it is impossible for anything of this kind to take place. Perhaps we have been mistaken all the time. We have supposed that the homœopaths have either been giving infinitesimal doses, or else, as we know, they give such doses as we do, and perhaps a little more. Now, it is said, "Let us meet them with kindness, and the people will see it, and come over to us." Some gentleman said here to-night, "We won't call in these people." But that rule won't work; if they are to go with us, we must go with them. I call attention to this paragraph in the new code: "In case of acute, dangerous, or obscure illness, the consulting physician should continue his visits at such intervals as may be deemed necessary by the patient or his friends, by him, or by the attending physician."

Dr. W. C. WEY, of Elmira: That matter was carefully considered by the committee, and the code was amended by the insertion of the word "consultation" before the word "visits."

Dr. J. W. S. GOULEY, of New York: Mr. President, we are

making no progress. There are evidently three parties—the old-code men, the new-code men, and the no-code men. I offer a substitute for the resolution of Dr. Squibb. *Resolved*, That the new code of ethics, enacted by the society during its session of 1882, be repealed.

Dr. PIFFARD: I rise to a point of order; this is simply the resolution on the floor stated negatively.

The point of order was sustained. Dr. Gouley appealed from the decision of the Chair.

Dr. T. H. SQUIRE, of Elmira, called for the reading of the resolutions of Dr. Squibb.

Dr. J. C. HUTCHISON, of Brooklyn, contended that Dr. Gouley's resolution was in order, inasmuch as it was intended as a substitute for the whole of Dr. Squibb's resolutions. The Chair then reversed the decision, and admitted Dr. Gouley's resolution as in order.

Dr. ROOSA: That is a device of the enemy. Dr. Gouley is opposed to the old code and the new code.

Dr. PIFFARD rose to a point of order that this substitute would be equivalent to putting the previous question. "Are we ready for it?" he asked.

Dr. ROOSA: This is a device of the enemy. Are we ready for this question until we rise from the Committee of the Whole?

Dr. GOULEY: Dr. Roosa is himself opposed to the new code. He told me so quite recently.

Dr. WEY rose to the point of order that this was a question not competent for the Committee of the Whole. The Chair decided that the committee could take whatever action it pleased.

Dr. GOULEY then withdrew his amendatory resolution, and presented a resolution that when the committee rise it report in favor of repealing the code of 1882.

Dr. S. O. VANDERPOEL, of New York: No change can be made in the by-laws without a two-thirds vote, and this is an attempt to change the by-laws by a majority vote.

Dr. GOULEY: We will have a two-thirds vote on this resolution. Be it understood that the vote on my resolution shall be a two-thirds vote.

The Chair ruled the resolution out of order.

Dr. C. R. AGNEW, of New York: I intend to be as brief as possible in saying what I have to say. A year ago this society, by a two-thirds vote, amended its by-laws to make them conform to the laws of the State. Efforts have been made to show that the action was hasty; such suggestions do not bear the test of criticism. Any effort for the good of man should be illumined by a higher light than the torch of persecution. Whence do we acquire the right to be here? Indisputably, from the State. No one but a regularly qualified medical man has a right to be here. The act of 1880, section 5, says: "The degree of Doctor of Medicine conferred," etc., "shall be a license for registration." That law defines what a doctor is, and this society has no power to make a definition. In the case of *The People ex rel. Gray vs. The Erie County Medical Society* (24 Barbour), Judge Marvin says: "The power given by statute to medical societies to make by-laws is not an arbitrary or unlimited power." "The by-laws must not be at variance with the general law of the land." Kent says "these corporate powers must be exercised reasonably," etc. The man whom the State has enfranchised, this society can not disfranchise. Pass the resolutions of Dr. Squibb; at tempt by your vote to repeal the new code, and you take action which will certainly be decided to be against public policy.

What is a code of ethics? What is the power of the State society to enact one? What are the relations of the State society and the county societies? The State society and the county society are distinct corporations. The State society is not so much a distinct society as a power of control. If a vote were

to be taken by counties, and members voted as instructed, a resolution might be carried which was repugnant to a majority of the members. Who instructs permanent members? Who instructs me? If county societies could instruct members, the majority of county societies could control the State society. The authority to pass the old rule and the new rule of consultation must be found in the law.

This is a very serious moment in the history of this society. These gentlemen, amiable as they may be, are endeavoring to lead this society not only to the edge of an abyss, but down into an abyss. Adopt the resolutions, repeal the present code, and re-enact the old one, and you put this society in opposition to the policy of the State, and you attempt to coerce the members of this society into an attitude in which no person who is capable of construing the laws will agree with them.

Dr. LUCIEN HOWE, of Buffalo: There seem to be two factions here, and some excellent reasons have been given on both sides. The code as it now stands should stand, but I am inclined to think that we have been hasty in taking this step. It is true that New York is a large State, but we must remember that we are not the only practitioners in this country. It is with a view of perhaps reconciling these two factions that I venture to offer a substitute for these resolutions.

Resolved, That the Code of Ethics of the American Medical Association be substituted for the one adopted by the society at the last meeting; but that the delegates to that association be instructed to advocate such modifications in the code as would be in accordance with a spirit of greater liberality, or, if advisable, to urge that it be abolished entirely.

The point of order was raised that this meeting was called specially for the consideration of Dr. Squibb's resolutions. The Chair decided that any discussion of subjects germane to the question was in order.

Dr. SQUIBB: My wish is that the freest discussion shall be had.

Dr. ROOSA: There are two parties here: there are those who are determined to vote down Dr. Squibb's motion, and those who support it.

Dr. WILLIAM P. SEYMOUR, of Troy: I admire Dr. Roosa very much. I wish he was on our side. Dr. Roosa can talk a good deal, and say a good deal at the same time. I think it a damning shame that a specialist should be the only man to stand up here and defend the practice of ages. It seems as if no one could get the floor here unless he was in favor of the new code. I have a telegram here from Dr. Lewis Sayre. I do not mean to mince matters. I agree with the statement that we are on the verge of an abyss, but I believe that, if anybody goes into it, it will be those who flaunt the flag of philanthropy. They have talked law till I am sick. They have talked law as if we were made for law. Good God! the laws were made for us.

Dr. Seymour continued at great length against the present generation of men and the degenerate condition of the State society, stating that when he was a young man it was the best men who were sent as delegates, but now the elections were manipulated like those of a political ward meeting. He stated that he had been connected with three medical colleges, or, as he contemptuously designated them, "doctor-mills," and had been invited to become connected with two others, and to resuscitate still another that was defunct, but he seemed to think it unwise to sustain or have aught to do with any of them.

The telegram from Dr. Sayre being called for, he read a dispatch stating that Dr. Sayre was confined to his bed; also a dispatch from Dr. Sayre to the effect that he had met in consultation a Dr. Baldwin, but there was nothing to indicate that Dr. Baldwin was a homœopath, and he did not know he was one till afterward.

Dr. HUTCHINSON: I am ready to step into the abyss, and consider it the proudest moment of my life. I desire to read a petition which has been circulated in the city of New York, and which I have been requested to present here. The petition has only been circulated for a short time, or there would have been more names on it, but it contains already one hundred and two names; among them are the names of such men as Alonzo Clark, Austin Flint, and others of like character. The petition opposes the new code. I desire also to read a letter from Dr. Sayre. (The letter was further explanatory of the circumstances of the consultation with the homœopath.)

Dr. AGNEW explained that he had not spoken disrespectfully of Dr. Sayre.

Dr. VANDERPOEL moved that the committee rise and report progress. Carried.

PRESIDENT JEWETT resumed the chair, and Dr. Hutchins, as chairman of the Committee of the Whole, presented the report.

Dr. ROOSA moved that the society proceed to vote on Dr. Squibb's resolutions, and called for the ayes and nays.

Dr. SQUIBB inquired whether the resolutions should be put as a whole or *seriatim*.

Dr. ROOSA: As a whole, Mr. President. The best thing for us to do after we defeat Dr. Squibb's resolutions is to pass my original resolutions abolishing all codes.

Dr. GOCLEY asked whether his substitute for Dr. Squibb's resolutions was not in order.

The PRESIDENT: It is not in order.

Dr. GOCLEY: I offer it now.

Dr. PIFFARD: I move the previous question on Dr. Squibb's resolutions.

Dr. SQUIBB: Is it in order to withdraw a portion of my resolutions?

Dr. ROOSA: I object.

Dr. ROCHESTER: I move that the vote be taken *seriatim*.

A member inquired if it was competent to call for a division of the question.

The PRESIDENT: Not at all.

A member appealed from the decision of the Chair.

The PRESIDENT: The gentlemen are referring to matters that took place in the Committee of the Whole.

A member inquired, "Can not the mover withdraw his resolutions?"

The PRESIDENT: Not at this time.

The motion that the previous question be now taken was put and carried.

The PRESIDENT decided that the resolutions must be put as a whole. The ayes and nays having been called for, the roll was then called. One or two members rose to explain their vote. One member, when his name was called, inquired whether members who were instructed by their county societies were at liberty to vote as they pleased or as they thought right.

The PRESIDENT replied that every member must settle such questions with his own conscience.

During the first part of the roll-call the ayes led very decidedly, but as the call proceeded the nays forged ahead, and the final result was 99 ayes and 101 nays.

The PRESIDENT very imperturbably announced that the resolutions, being in the nature of an amendment to the by-laws, required a two-thirds vote to sustain them, and, not having received such a vote, they were lost.

Dr. ROOSA: It is well known that those of us who have succeeded are divided into two parties. A portion of us favored the new code. A larger portion, I believe, took the position of the following resolution:

The Medical Society of the State of New York, in view of the apparent sentiment of the profession connected with it, here-

by adopt the following declaration, to take the place of the formal Code of Ethics, which has, up to this time, been the standard of the profession of the State.

With no idea of lowering in any manner the standard of right and honor in the relation of physicians to the public and to each other, but, on the contrary, in the belief that a larger amount of discretion and liberty in individual action, and the abolition of detailed and specific rules, will elevate the ethics of the profession, the medical profession of the State of New York, as here represented, hereby resolve and declare that the only ethical offenses for which they claim and promise to exercise the right of discipline are those comprehended under the commission of acts unworthy a physician and a gentleman.

Resolved, Also, that we enjoin the county societies and other organizations in affiliation with us that they strictly enforce the requirements of this code.

Action on this resolution was postponed to next year.

Dr. JOHN G. ADAMS, of New York, offered a protest against the action of the society, charging that it had "assumed an attitude and adopted a policy in direct and open hostility to the honor and the best interests of the medical profession."

The protest was received, and ordered on file.

SECOND DAY.—WEDNESDAY, FEBRUARY 7TH.

Morning Session.

The society assembled at 10 A. M., and was called to order by the President. Prayer was offered by the Rev. Irving Magee, formerly of the Lutheran Church, of Albany.

The Treasurer, Dr. C. H. Porter, reported a balance on hand of \$1,264.21. The report was referred to a committee composed of Drs. Perkins, Ely, and Hopkins for audit.

Dr. Porter, as trustee of the Merritt H. Cash Prize Fund, offered a report, which was accepted.

The Committee on By-laws and Hygiene reported that they had nothing to present.

Dr. F. R. SURGEIS, of New York, read the report of the Committee on Legislation, recommending the passage by the Legislature of a bill, which he presented, to regulate practice, and throw additional safeguards about the practice of medicine. The committee also offered the following resolution:

Resolved, That the sum of five hundred dollars be appropriated by the Medical Society of the State of New York, to be drawn upon through the Treasurer upon the written order of the chairman of the Committee, to meet the necessary expenses incident upon the passage of any acts affecting medical matters, which the Committee on Legislation may be instructed by the society to attend to, and for any contingent expenses; and whatever surplus there may be shall be returned to the treasury of the society.

Dr. SURGEIS spoke of the necessity of this appropriation, and of having an agent at the Capitol to look after legislation affecting the medical profession. During the year the Buffalo College of Physicians and Surgeons had been closed, and there was a prospect of the United States Medical College of New York being closed. At the last session of the Legislature a bill had been snaggled in to legalize them.

Dr. H. D. DIDAMA asked if any provision was made in this resolution for the prevention of the passage of obnoxious bills.

Dr. SURGEIS: The resolution reads, that this sum of money shall be drawn upon to meet the expenses incident upon the passage of acts, etc. Of course, the committee would look after the non-passage of improper bills.

Dr. H. R. HOPKINS moved that the report be adopted, and said that the recommendation to have an officer on guard at the Legislature was of pre-eminent importance. In the closing

hours of the last session of the Legislature a bill was introduced without a word in it about medicine, which yet had a very important bearing upon the interests of the profession.

The report was discussed at some length, the tenor of the remarks tending to show that the registration law of 1880 was inadequate to meet the requirements of the profession, as under it quacks of all kinds could register and thereafter deem themselves legally qualified to practice. One of the members remarked that in his county an Indian doctor rode in the other day in his chariot and adorned with war-paint and feathers. He registered, and was now considered a legally qualified practitioner, and placed on a footing with other members of the medical profession. That the present law was inefficient was shown in the fact that a woman graduate of a New York college, said to be a notorious abortionist, brought a diploma to a county society, registered, and was now deemed qualified to practice. There was no principle connected with the matter of legislation which had not been sufficiently dealt with here. This society had never asked of the Legislature protection for an educated profession. To his judgment the society was in a position to go to the Legislature and say that it had no opinion to protect in regard to the action of medicine, but it had the opinion that the people would be better off by having protection for the education of the profession. It needed a law which should say to the people, "No matter where a man gets his education, if he can come before the board and show a proficiency, he shall be licensed."

Dr. VAN DE WARKER: The law of 1880 protects the quacks.

Dr. SURGEIS: When the gentleman says that the law of 1880 protects the quacks, he is mistaken. We have made sixty odd prosecutions, of which only three have failed. The law of 1880 is the surest and safest way to get hold of quacks.

Dr. W. M. SMITH: The mere registration in the County Clerk's office does not make a man a qualified practitioner.

D. W. C. WEY seconded the motion to adopt the recommendations of the Committee on Legislation. The motion was carried.

A letter was received from Mr. Clark Bell, of the New York Medico-Legal Society, which was read by title and referred to the Business Committee.

A communication was read from Chancellor Pierson, of the Board of Regents, to Dr. Vanderpoel, relative to the appointment of a Board of Examiners. The communication stated that a board was appointed in 1875, some of the members of which had died, others resided in different parts of the State, and it was difficult for them to come together. In view of this, the Board of Regents had deemed it advisable to take action, requesting the matter to be brought to the notice of the State society, and requesting the appointment of a committee to confer with the Board of Regents and suggest suitable persons as examiners.

The communication was received, and the following resolution adopted:

Resolved, That a committee of three, consisting of Dr. S. O. Vanderpoel, of New York, Dr. E. M. Moore, of Rochester, and Dr. A. Jacobi, of New York, be appointed to confer with the Board of Regents in reference to medical examinations under chapter 746 of the Laws of 1872, and that the committee have power on behalf of this society to recommend suitable persons for examiners.

Dr. HUTCHISON, chairman of the Committee on the President's Address, reported that, in the judgment of the committee, (1) legislative enactments for the regulation of the medical profession were not to be desired. We had thus far seen but little advantage resulting from legislative action in matters relating to our status as individuals or as a society; (2) there seemed to be at present no better method for elevating the standard of

medical education and the efficiency of our medical schools than for physicians to discourage the study of medicine by those whose preliminary education was deficient, and to use their influence to guide students to those medical schools which furnished the most thorough course of instruction; (3) we did not consider that examinations conducted by a State Board of Examiners could be made so free from political influences as to be recommended to this meeting; (4) the active efforts of our State Board of Health deserved our hearty support; and (5) expressing an opinion adverse to changing the time-honored custom of delivering the annual address in the Capitol, but stating that, in the judgment of the committee, the annual address would be dispensed with, as the President's views on matters of interest could be incorporated in the inaugural address.

The report was accepted and ordered on file.

Dr. A. JACOBI, of New York, presented the report of the committee to co-operate with the Society for the Prevention of Cruelty to Children. The recommendation to isolate scarlet-fever patients, adopted by this society last year, had been brought by him before the New York society. Finding that no suitably isolated hospital existed in New York city, the committee recommended the erection of a suitable hospital at the foot of Sixteenth Street. The report of the committee was accepted.

The secretary read the report of Dr. J. W. WHITBECK, censor of the College of Medicine of Syracuse University. The report was accepted and placed on file.

The report of Dr. W. M. CHAMBERLAIN, of New York, delegate to the New Hampshire Medical Society, was referred to the Publishing Committee without reading.

Dr. PAUL F. MUNDÉ, of New York, read a paper on "THE ETIOLOGY AND TREATMENT OF NON-PERIPHERAL UTERINE HÆMORRHAGE."

He limited his remarks to several features not hitherto recognized.

He spoke first of superficial non-puerperal erosion of the cervix uteri. Such cases might have been treated empirically by astringents, rest, and ice without relief; and upon examination the eroded cervix was brought into view, of a bright red color, and bleeding readily on being wiped with even cotton. The erosion at different times resembled the tomato, the raspberry, or the strawberry. When depending upon cervical catarrh it was found in virgins, in the married, and in multiparæ. In the poorly nourished it occurred more frequently. In addition to the intermenstrual discharge, the menstrual flow itself was prolonged. If occurring in the young girl, the patient was much annoyed by the staining; and the married patient feared injury to her husband. The diagnosis was easier than the cure. The surface should be exposed by the speculum, carefully cleansed and wiped dry, and a solution of nitrate of silver, a drachm to the ounce, should be applied; iodoform was then blown upon the surface and a pledget of cotton dipped in glycerine laid over all. An injection of sulphate-of-zinc solution might be used for three or four days, and a milder solution of nitrate of silver, say half a drachm to the ounce, might be applied through the speculum afterward. It might be necessary to use nitric acid, chromic acid, or pyroligneous acid, followed by astringent injections. Galvanism often gave good results. The removal of the hypertrophied glands was usually essential to the treatment. It was well to notify the patient that the cure was certain, but she must persevere for several months. Graft healthy membrane on the surface if required. A protracted menstrual flow without continuous intermenstrual discharge might depend upon superficial erosion and demand local treatment, even during the menstrual period.

2. In hemorrhage due to lacerations of the cervix, the bleeding from granulations was not dangerous, but annoying.

The slightest touch would cause hemorrhage, which might follow coition, or even walking. Snip off granulations or scrape with a curette, and use caustics, astringents, and, if necessary, perform trachelorrhaphy. So long as the cervical canal gaped, a return of hemorrhage was probable.

3. Menstrual hemorrhage, or intermenstrual oozing, when due to subinvolution, should be treated by hot-water injections twice daily, and by the internal use of ergot, sulphate of iron, strychnine, or viscum album. Subinvolution was a very common cause of cervical hemorrhage.

4. Hemorrhage in virgins was frequently due to hyperæmia of the endometrium, and was controlled by local applications of iodine when ergot had failed. Tonics might be required to restore to health.

In cases of pin-hole external os, menstrual blood was prevented from free escape, and, being lodged above the point of exit, it continually dribbled. Make an incision in four directions, turning the flaps over to an open funnel shape, thus allowing escape of the retained blood, and all oozing would cease.

Dr. E. VAN DE WALKER considered the paper one of the most valuable and practical that he had listened to for a long time.

He had used the actual cautery with advantage. It was nearly painless, and produced a revolution in tissue metamorphosis; one week would accomplish what would require weeks of treatment by nitrate of silver.

Dr. B. F. SHERMAN, of Ogdensburg, had used pure phenol (Squibb's) saturated with iodine for eroded cervix, hyperæmia, and a granular condition of the endometrium; it produced acute pain, which lasted but for a few seconds. When healing commenced, he had used the galvanic battery, from two to six cells, which lessened hyperæmia, and promoted healing more rapidly than any other treatment he had used.

Dr. F. A. CASTLE presented the following:

"Resolved, That the Committee on Publication be requested to publish in future volumes of the transactions of this society, as an appendix, a revised list of the registrations of physicians in the offices of the county clerks of this State.

"Resolved, That the sum of \$150 be appropriated to cover the expense of obtaining the necessary information.

After a long and rambling discussion, the resolution was tabled.

Dr. DIDAMA: Several gentlemen felt a little aggrieved by the action of the society last evening, and said they wouldn't have anything more to do with it. I hope that no gentleman will carry out the threat which he made when we were all warm. In order that we may have something to collect us next year, I offer this:

Believing that the so-called new Code of Ethics is opposed to the opinions of the majority of the medical profession throughout the world, as expressed in the action of county, State, and national associations, and in discussions in medical journals; and believing also that this so-called code, by removing wholesome restraints, encourages a spirit of lawlessness and sanctions fraud; that it is hurtful not only to the profession, but to the public; that its adoption sent a thrill of joy through the heart of every quack in the land, and gave pain to the wisest and best of our associates in the regular profession, I offer the following amendment to the by-laws:

"Resolved, That all action taken at the annual meeting of 1882, in regard to changing the Code of Ethics, be rescinded, leaving the code to stand as it was before said action was taken.

Dr. Wey moved to table, saying that the question was already covered by the resolution adopted last evening and now lying on the table for action next year.

Dr. DIDAMA: This is an amendment to the by-laws, and must necessarily lie on the table.

Dr. ROOSA: This motion is out of order. It is an insult to the majority of this society. We insist that this battle shall not be continuously fought. To continually bring up this subject, heaping epithets upon us who are in the majority, is entirely improper.

Dr. DIDAMA: I am responsible for what I have said. I said, "I believe this to be true," not "it is true." These gentlemen have a little brief authority; they may not have it next year.

Dr. ROOSA: If the gentleman will present this in what we conceive to be an honorable manner, it may be presented every year until the year 2000.

Dr. DIDAMA: I claim the right to offer any amendment.

Dr. ROOSA: Without a stump speech inside of it.

Dr. WEY: I take the ground that it isn't an amendment in any sense.

Dr. ROOSA: We call for the ayes and nays, because it is evident that the understanding between us and Dr. Squibb has been broken.

Dr. VAN DE WABKER: The society is not packed this morning.

Dr. SQUIBB: I object to Dr. Roosa's statement that there was any understanding.

Dr. ROOSA: I do not see how any honorable man can approve of bringing this up again now.

Dr. ELSBERG asked Dr. Didama to withdraw the preamble, and simply propose the amendment to the by-laws.

Dr. DIDAMA: You do not act on a speech; you act simply on my amendment to the by-laws when it comes up. I simply made a written speech instead of an oral one. I have made my speech and I can not take it back, because it is spoken, and you can not help yourselves.

Dr. ELY asked Dr. Didama to read again what he desired to bring up next year. He understood that this whole paper was to be brought up. It seemed to him it was derogatory to the action taken last night.

Dr. DIDAMA: I did not propose to bring up anything next year except the resolution.

The whole subject was laid over until next year.

An obituary notice of Dr. S. M. Van Alstyne, of Richmondville, by Dr. A. Vanderveer, was read by title.

Dr. ELSBERG read a paper entitled "The Hypertrophic Form of Nasal Catarrh and its Treatment." The surgical treatment which he had formerly introduced by evulsion and cutting, though frequently successful, was so often unsuccessful as not to be recommended. Galvanism was successfully used in the removal of tissue. He commended the plan of transfixing hypertrophied tissue with a needle, and removing it with the *écraseur*; he preferred pinching it up with a forceps, instead of transfixing it with a needle. He approved of Dr. A. H. Smith's tubular scissors; the main objection to their use was the hemorrhage from cutting. He exhibited a slender forceps with canulated blades combined with an *écraseur* loop, which he had found a satisfactory instrument.

Dr. H. KNAPP, of New York, read a paper on "An Eighth Series of One Hundred Consecutive Cataract Extractions." In the hundred cases of cataract extraction there were ninety good results, six moderately good, only two positive failures. A septic healing of the wound was not enough; we must have primary union. The antiseptic era had not advanced ophthalmology. We were already beyond it. There was no sepsis in the eye if we had a clean operation. Rest was the next condition; the patient ought to lie as still as a mummy if he could do it. He remembered laying a frog's cornea on the microscope, and found that the movable cells went to the margin. There were no bac-

teria in the eye, but you had in half an hour inflammatory action of the part. The lymphoid cells migrated to the margin. This was the cause of the physical injury producing suppuration.

Afternoon Session.

In the absence of the President and Vice-President, Dr. WEY was called to the chair.

Dr. ROOSA read a paper on "The Injudicious Use of Quinine." He said that, in a paper read by him in 1874, he called the attention of the profession to possible dangers to the organ of hearing by the use of quinine. This led to a series of experiments upon human subjects by himself, and on animals by Dr. Hammond. Quinine was particularly harmful to ears which were already congested and predisposed to deafness. The primary effect of moderately large doses was to produce congestion of the retina and of some parts of the ear; there was vascular injection of the auricle, the auditory canal and papilla; there was tinnitus aurium, and a sense of exhalation. It was harmful to ears already congested, and, in rare instances, produced temporary deafness and blindness. In some cases it might have been necessary to take the risk, but he believed that this drug was sometimes administered in cases where it proved harmful. In pyæmia, quinine appeared to be only harmful—unnecessary, injudicious, and possibly dangerous. Quinine was used freely in households in febrile conditions and catarrhs. From ten to fifteen grains were often taken with no other provocation than symptoms of a cold in the head. He believed it was dangerous when taken on the patient's own prescription. He admitted that in malarial fever and intermittent neuralgia quinine was necessary, but in the exanthemata from ten to fifteen grains daily would aggravate the condition, by shutting up the emunctories of disease-poison.

In the various febrile diseases, reduction of temperature was regarded as the desideratum; but sudden reduction of temperature had induced or aggravated collapse. The natural reduction of temperature might be better than reduction induced by quinine. A cold in the head, he believed, was aggravated by the use of quinine. In all colds affecting the aural passages, quinine was especially harmful. The practice of taking quinine to abate colds had an authority, but he disapproved of it. Whenever a drug as powerful and dangerous as quinine became the property of the laity, we might expect to see injury result from its use. In severe cases of fever we might be justified in taking the risk of the use of the drug.

Dr. T. R. POOLEY, of New York: My experience confirms Dr. Roosa's view of the effect of quinine in aural and retinal disease and in pyæmia. When we have exacerbations in the throat and pharynx, the symptoms are aggravated by the use of quinine. In a case of pyæmia following an operation for hæmorrhoids, when large doses of quinine were given, the delirium was made worse. In the use of excessive doses of quinine there is a form of amblyopia induced.

Dr. JACOB: There was one remark of Dr. Roosa's which struck me. He says that the use of quinine induced collapse and lower temperature. May it not have been that collapse was setting in already? The quinine in such cases would not retard the decline of temperature and collapse which had already set in. My main objection to Dr. Roosa's remarks is that he did not make the distinction between pyæmia and septicæmia. It may be that he spoke of septicæmia, and only substituted the word pyæmia. I do not know of the presence of a poison in pyæmia. I do know of a poison in septicæmia. In pyæmia, pus is absorbed from an abscess or ulceration, and deposited elsewhere. Quinine prevents the migration of corpuscles, hence prevents metastasis of pus. Septicæmia may not be affected by quinine.

Dr. W. M. SMITH, of Syracuse: I find that cinchonine affects my vision much more than quinine does. Cinchonine diminishes the urinary secretion, and produces dryness of the mouth. I have a patient to whom I was giving a moderate dose of quinine, which made her decidedly deaf, while cinchonina did not. Cinchonidine abolished taste; canned peaches felt merely cold in the mouth, without flavor.

Dr. ROOSA: Experiments by myself and by Dr. Hammond, and by various German investigators, show that the primary effect of quinine is congestion, vascularity, and exhilaration; the secondary effect is depression; and this is one of the reasons why quinine is dangerous in depressing diseases. I don't believe in the distinction between pyæmia and septicæmia. I believe that there is a poison in pyæmia more than the mere transfer of pus, which should be properly eliminated, just as in septicæmia. There are conditions in septicæmia which are exactly like those in pyæmia. I once saw, in consultation, a child with aural disense, tenderness of the mastoid, and a red drum-head. The symptoms were represented to me as meningeal, or typhoid. Local antiphlogistic treatment would have relieved. When I opposed the use of quinine, the answer was given, "The temperature is 104°." Contrary to my advice, quinine was given, with fatal result; which result, of course, might have followed antiphlogistic treatment. I admit that the secondary effect of this drug is one of depression, but I insist that the primary effect is one of congestion.

Dr. HENRY W. WILLIAMS, of Boston, delegate from the Massachusetts Medical Society, related cases of ORBITAL CELLULITIS RESULTING FROM ERYTHRELA.*

Hamlin, of Middleville; J. D. Lomax, of Rensselaer County; G. E. Lyon, of West Troy; W. C. Cooper, of Troy; William Stevens, of New York; and D. H. Cooks, of Albany.

Evening Session.

ANNUAL ADDRESS OF THE PRESIDENT.

SOME OF THE PERIODS OF LIEBIGESIM PRESENTABLE DISEASES.

THIRD DAY.—THURSDAY, FEBRUARY 8TH.

Morning Session.

Dr. SMITH, from Committee on Publication, reported that the delay in issuing the volume of Transactions for 1882 was due to the non-return of proof-sheets by the authors.

Dr. HOWE, of Buffalo, introduced the following as an amendment to the By-laws: "That the Code of Ethics of the American Medical Association be substituted for the one adopted by this society in 1882, and, having thus gained the unquestioned right to representation, that our delegates be instructed to advocate such modification of that code as shall be in accordance with a spirit of greater liberality, or, if advisable, to urge its entire abolition."

The resolution was laid over for action at the next annual session.

Dr. PORTER, of Albany, offered a resolution that a committee be appointed to confer with the Capitol commissioners concerning appropriating a room in the new building for the use of the State Medical Society. Adopted, and Drs. Porter, Bailey, and Mosher, of Albany, were appointed.

Dr. Porter also offered a resolution that a committee be appointed to consider the propriety of publishing, and to publish, if deemed desirable, the "Transactions," from 1837. Adopted, and Drs. W. M. Smith, C. H. Porter, and F. S. Curtis were appointed.

OFFICERS FOR ENSUING YEAR.

The Committee on Nominations submitted the following report, which was adopted:

For President.—Alexander Hutchins, of Brooklyn.

For Vice-President.—H. G. P. Spencer, of Watertown.

For Secretary.—William Manlius Smith, of Syracuse.

For Treasurer.—Charles H. Porter, of Albany.

For Censors.—SOUTHERN DISTRICT: J. W. D. Gouley, Austin Flint, F. D. Castle—all of New York.

EASTERN DISTRICT: C. E. Nichols, M. H. Burton, W. S. Cooper—all of Troy.

MIDDLE DISTRICT: Alonzo Churchill, S. G. Walcott, J. K. Chamberlayne—all of Utica.

WESTERN DISTRICT: C. C. Wyckoff, Thomas F. Rochester, F. F. Hoyer—all of Buffalo.

Committee of Arrangements.—S. B. Ward; J. S. Mosher, of Albany; W. S. Ely, of Rochester.

Committee on By-Laws.—W. C. Wey, of Elmira; N. G. Pitford, of New York; William Manlius Smith, of Syracuse.

Committee on Hygiene.—F. V. Steadland, of Rochester; Stephen Smith, of New York; Jacob S. Mosher, of Albany; P. R. H. Sawyer, of Bedford; Caleb Green, of Homer; Edwin Hutchinson, of Utica; Theodore Denney, of Auburn.

Committee on Legislation.—Jacob S. Mosher, of Albany; F. R. Sturgis, of New York.

Committee on Medical Ethics.—C. R. Agnew, of New York; E. M. Moore, of Rochester; S. Oakley Vanderpoel, of New York.

Committee on Prize Essays.—Thomas F. Rochester, of Buffalo; William S. Ely, of Rochester; W. W. Potter, of Buffalo.

Committee on Publication.—William Manlius Smith, of Syracuse; Charles H. Porter, of Albany; George J. Fisher, of Sing Sing.

Censor for the College of Medicine, Syracuse University.—C. S. Starr, of Rochester.

For Permanent Members.—*First District:* F. P. Foster, New York; Lawrence Johnson, New York; Alfred C. Post, New York; David Webster, New York; (J. H. Hobart Burge, Brooklyn); John Byrne. *Second District:* J. J. Linson, Tarrytown; E. F. Quinlan, Monticello. *Third District:* S. B. Ward, Albany; C. E. Willard, Catskill. *Fourth District:* A. J. Browne, Herkimer; A. M. Phelps, Franklin. *Fifth District:* J. N. Goff, Cazenovia; J. D. Spencer, Watertown. *Sixth District:* L. D. Witherill, Union; D. W. Birge, Peach Orchard. *Seventh District:* J. B. Chapin, Millard; Alfred Mercer, Syracuse. *Eighth District:* W. W. Potter, Buffalo; J. W. Whitbeck, Rochester.

For Honorary Members.—T. J. Turner, of the U. S. Navy and National Board of Health; William Goodell, of Philadelphia; Lockhart Robinson, of Edinburgh.

Eligible to Honorary Membership.—W. Bronson, of New Canaan, Connecticut; Dr. Cabell, of the University of Virginia; Richardson, of the University of Pennsylvania; Professor James T. Whittaker, of Cincinnati, Ohio; W. H. Hingston, of Montreal.

Delegates to State Medical Societies.—*Massachusetts:* George C. Smith, of Rondout; Brush, of Utica; P. V. S. Prayn, of Kinderhook; George G. Hopkins, of Brooklyn. *New Hampshire:* William M. Chamberlain, of New York. *New Jersey:* Joseph C. Hutchinson, of Brooklyn; Robert Newman, of New York. *Ohio:* Thomas R. Pooley, of New York. *Pennsylvania:* H. C. May, of Corning; Sol Van Eften, of Port Jervis; T. D. Strong, of Westfield. *Vermont:* D. Lyon, of Plattsburg; A. J. Long, of Whitehall; C. C. F. Gay, of Buffalo. *Connecticut:* P. V. R. H. Sawyer, of Bedford; E. V. Stoddard, of Rochester; George Douglas, of Oxford. *Canada:* B. F. Sherman, of Ogdensburg; H. G. P. Spencer, of Watertown; L. E. Felton, of Potsdam; James C. Hutchinson, of Brooklyn; R. J. Robb, of Amsterdam.

Respecting the delegates to the American Medical Association, the committee reports that it deems it inexpedient, at present, to name any delegates to that body.

The society then adjourned till the first Tuesday in February, 1884.

Reports on the Progress of Medicine.

QUARTERLY REPORT ON PREVENTIVE MEDICINE AND MEDICAL JURISPRUDENCE.

No. I.

By ANDREW F. CURRIER, M.D.

THE RELATIONS OF METEOROLOGICAL PHENOMENA TO MAN. — Dr. J. W. Tripe ("Brit. Med. Jour.," Nov. 4, 1882) remarks that sufficient data are wanting for a complete inquiry upon this subject. In the paper which he read before the Society of Medical Officers of Health, October 20, 1882, he did not attempt to cover the entire scope of the subject. The influence of ocean currents

upon climate is well-known, and the author referred particularly to its influence upon an insular country like England. The variations of atmospheric pressure, temperature, and humidity have a marked influence upon the physical condition. This may be seen in the peculiar sensations experienced at elevations of eight thousand feet or more. Change of function quickly occurs to one who removes to such an altitude. Hence the reasonableness of requiring such a change of residence for certain classes of patients. Variations of pressure and temperature exert a considerable effect upon the circulation of air contained in the soil, which is atmospheric air mixed with carbonic acid, marsh gas, sulphuretted hydrogen, etc. Rain causes a rapid escape of air from the soil. It has been found that, in localities where the ground-water is only five feet below the surface, ill-health prevails among those who live in that vicinity. Typhoid fever has frequently broken out after a heavy fall of rain succeeding a drought has washed the germs of disease into wells whose water is used for drinking purposes. Well-drained soil has lessened the mortality in districts previously affected with phthisis. The presence or absence of ozone in the atmosphere has an important bearing upon the quality of the air for inhalation. The development of bacteria is influenced largely by certain conditions of temperature, and, as Tyndall has shown, the influence of light upon these low forms of existence is by no means unimportant.

THE PREVENTION OF ZYMOTIC DISEASES.—In the "Lancet" for October 28, 1882, Dr. Thomas M. Dolan remarks that the scientific physician should approach the study of disease as a naturalist does that of animals and plants. The germ theory should be studied by the light of evolution. The author outlines the following plan of what should be done: 1. The genesis of contagium vivum. This will include the life-history of each form, applying the general principles of evolution to the genesis of each individual disease germ. 2. Reproduction, whether slow or rapid, whether from seed forms or by fission. The experiments of Dallinger and Drysdale on the life-history of some monads will serve as an example. 3. Development, maturity, and decay. Duration of life, morphology, physiology, etc. 4. Laws controlling contagion. Special seasons of activity; the influence of environment upon each disease; sanitary conditions, and relation to physical phenomena; influence of oxygen in the atmosphere; heredity; variations; crossing, or transmutation; susceptibility; relation of the habitat; progressive development of types; application of analogy of laws regulating plant life. 5. Distribution in its geographical relations. Influence of climate, warmth, moisture, winds. Effects of human interference. Distribution of disease in zones. General method of diffusion. 6. Geological distribution. Nature of soil, rock, drainage, etc. As to general preventive measures, he would establish a sanitary cordon around the world, with bureaus for investigation in all the great cities. From the statistics which will thus be secured, general conclusions can be drawn. His leading ideas are: 1. That the sanitary authorities of each country should work on one uniform plan, and under central direction. 2. That all sanitary authorities in every country should interchange maps, etc., and that the methods of recording disease should be the same.

THE ARTIFICIAL FEEDING OF INFANTS.—Dr. T. Hryntschak ("Arch. f. Kinderheilk.," iii, 11-12, 1882) thinks that two conditions are indispensable in any substance which is to be used as a substitute for breast-milk. 1. It must resemble breast-milk as nearly as possible in the quantity and quality of its nutritious elements. 2. It must be well borne alike by healthy and by sick children with reference to disturbances of digestion. Lactin has been recommended as answering these conditions, and experiments have been made by the author with the view of

testing the validity of such recommendation. The lactic is prepared in packages containing each twelve grammes. This quantity is to be dissolved in a quarter of a litre of hot water, and to this is to be added a quarter to half a litre of cow's milk, when the preparation is ready for use. The quantity of milk-sugar which is contained by one thousand grammes of the mixture is forty-two and nine tenths grammes, against forty-three and sixty-four hundredths grammes in breast-milk. This would seem to support the manufacturer's statement that the artificial preparation was nearly identical with breast-milk. That statement is disproved, however, by the addition of rennet to breast-milk, and to lactic. When added to the latter, it curdles in a few minutes, just as ordinary watered milk would do, and, after standing a short time, a tolerably compact coagulum will be formed. When added to breast-milk, on the contrary, there is no curdling at all, or only barely perceptible flecks in the course of thirty-six hours. Besides, there must be a difference between the casein of cow's milk and that of breast-milk. The lactic is prepared from whey, and the salts which it contains, and which are in different proportion from that which is in breast-milk, must render its action different from the latter. The chief constituents of lactic are milk-sugar, a starch-containing substance, the salts of the whey of cow's milk, bicarbonate and chloride of sodium. Its effect upon the human system must be the same as that which would be produced by an equal quantity of cow's milk mixed with rice or barley gruel, and with an equal quantity of milk-salts added. A table of seventeen cases is given in which the lactic was used. The patients varied in age from three weeks to one year, and were of the usual character met with in polyclinic practice. Most of them were affected with intestinal disorders when brought for treatment. No positive improvement could be attributed to their treatment with lactic. If the weight increased rapidly at first, and the stools became natural, in a short time the effect of the treatment disappeared in several of the cases, and the former troubles recurred. In other cases a change to ordinary watered and sweetened milk was made, and the patients seemed to thrive quite as well upon it. Even when children did well, as to weight and general condition, when fed upon cow's milk and lactic, they were, as a rule, troubled with diarrhoea, due, doubtless, to the great quantity of salts in the preparation. The author concludes that lactic does not fulfill the conditions stated in his two propositions at the beginning of the paper, is not, therefore, an ideal preparation, and, in some cases, will do harm. As a general rule, proprietary mixtures must be received by the physician with distrust.

EXAMINATIONS OF WATER AND AIR. Mr. ROBYN HITELOCK ("Jour. of the Franklin Institute," Nov., 1882) proposes the following question: Under what circumstances can a chemist condemn a water for household use? Waters containing chlorides, nitrites, and other substances, indicative of contamination with sewage or other organic matter, are unsafe, though it is seldom that disease can be attributed to their use. Hence, it must be another element which produces such diseases as typhoid fever. This is generally conceded to be a living microscopical germ, which develops and multiplies in the water; but this is quite out of reach of a chemical analysis. The drainage from vaults containing human dejecta is not necessarily unhealthful. It is when this drainage contains disease germs that the mischief is done. In regard to the examination of air, there is much confusion as to the value of results. This is without reference to the known injurious influence of carbon dioxide, carbonous oxide, and other noxious gases. Air which is chemically pure may be a vehicle of contagion, and that which is chemically impure may be harmless as to contagion. Thus ammonia, sulphuretted hydrogen, and other gases which arise from the decomposition of refuse matter in the streets, will not breed a

pestilence, so long as the germs of disease are not present with them. It is probable, however, that the development of these germs is favored when the other conditions obtain. These germs may be collected from the air by means of cotton. The author sums up the result of experience as follows: We have no means of determining when a water which analysis shows is liable to become a carrier of disease does become active in its dissemination, nor can we yet determine whether the air we breathe is or is not loaded with the germs of disease. It is to be considered a national misfortune that the National Board of Health has been unable to secure an appropriation adequate to continue its work and the publication of its bulletin. The great decrease in the death-rate in England and Wales since 1841 is considered to be due largely to the effect of sanitary laws upon the prevalence of certain zymotic diseases. Another important and kindred subject pertains to the efficiency of disinfectants. The agent used must be strong enough to destroy the living germ or to neutralize the chemical poison. Ordinary aerial disinfection is utterly useless. The only efficient method in the sick-room consists in the immediate disinfection of all refuse, and thorough ventilation.

THE ANALYSIS OF WATER.—In the same journal, Mr. Reuben Haines remarks that many difficulties accompany such investigations. The substances found, whether living or dead, can not always be identified, and some of them are evidently capable of doing harm, even when present in very small quantities; different opinions, too, are expressed by chemists regarding the wholesomeness of waters, according as they have followed different methods of analysis. Wanklyn's Ammonia Method is extensively used; but other chemists are not entirely agreed as to its meaning in different parts of his book of instruction. The method appears to be simple, and easy to follow; but experience has shown that many precautions not stated in the book are necessary, which lead to confusion. The author offers this paper as his interpretation of the method. The retort and the condenser should be connected by means of a short piece of wide rubber tubing, which should be fastened upon each with a piece of cord. It is unnecessary to say that all the apparatus should be thoroughly clean. "Bumping," or boiling over, of the water in the retort may be best prevented by watching carefully, and quickly removing the Bunsen burner as soon as a tendency to do this is manifest, also by allowing the distillation to proceed more slowly. Each separate distillate should be accurately measured, and a permanent record made of the quantity of ammonia which it contains. If more than three fourths of the total quantity of free ammonia is obtained by the first distillation of fifty cubic centimetres, the water would at once be condemned, if it comes from a shallow well or spring. An important part of the process is the use of the Nessler test for colorimetric purposes, and which is, of course, entirely unavailing, if the experimenter is color-blind. The alkaline permanganate solution which is used in the process must be entirely free from ammonia. This result may be obtained by dissolving the required quantity of caustic potash and of permanganate in separate portions of distilled water. They are then to be mixed, diluted to fifteen hundred cubic centimetres, and rapidly boiled in a capacious flask over a Bunsen burner down to five hundred cubic centimetres. A further dilution to twelve hundred cubic centimetres is then to be made with distilled water, and this is to be boiled down to nine hundred cubic centimetres. After this has cooled, sufficient water, which has been redistilled with alkaline permanganate until free from all traces of ammonia and organic matter, must be added to make a litre of the mixture. The remaining particulars are too technical to be of general use.

THE SPOILAGE OF GRAIN.—A writer in the "Sanitary News" for November 1, 1882, details a series of experiments

by Mr. George E. Waring, Jr. Several traps were tried, among them the *S*, the *Bower*, the *Garland*, the *Paragon* of Brandeis, and the *Mercury Seal* of Nicholson. These were placed in succession at the end of a one-and-a-quarter-inch horizontal waste-pipe which emptied into a soil-pipe near its base through a four-by-two-inch Y branch. Vents in the waste-pipe were alternately opened and closed. Above the waste-pipe, and discharging into the soil-pipe on either side, were a bath-tub and a water-closet. The soil-pipe was four inches in diameter, extended upward several feet, and was furnished with a flap-valve at the top, which was closed during some of the experiments. The experiments were as follows: First, the bath-tub was filled, and its contents were alone discharged by opening the two-inch valve. Next, the water-closet bowl was filled and discharged. Then both were filled and discharged together. When the soil-pipe was closed at the top, and no vent left in the waste-pipe, all the traps were completely siphoned. When the vents were opened, one after another, and the bath-tub alone was emptied, the *S* trap lost from half an inch to an inch of water. It lost from an eighth of an inch to an inch with no vents open and the valve upon the top of the soil-pipe partly open. With the valve entirely open, Bower's and Garland's traps lost no water, and no motion of their ball-valves was perceptible. If the bath-tub and the water-closet were discharged together, more water than in the former instance was lost from the *S* trap, but the seal (three inches deep) was not broken. In this instance, also, no water was lost from Bower's and Garland's traps. With the soil-pipe open at the top, and the vents opened successively, when the bath-tub was discharged, either alone or simultaneously with the water-closet, neither of the three traps last mentioned lost any water. The experiments were repeated after extending the soil-pipe by fifty feet. The traps lost more water, but were not siphoned. Other experiments were also made, but the summary of the entire series is as follows:

1. The flow of drainage through a four-inch vertical soil-pipe, not ventilated at the top, produces a very strong suction on branch-pipes the mouths of which it passes.
2. The opening of the four-inch soil-pipe at the top practically prevents such suction, even when the upper part of the pipe is seventy feet in length, and circuitous in its course.
3. If each bath-tub, wash-basin, sink, etc., wastes by an independent outlet to a branch of a four-inch soil-pipe, open at the top, the siphoning of even ordinary *S* traps having more than one inch of seal is not to be apprehended.
4. If one vessel discharges into a branch leading from another vessel, the discharge of the latter may produce a suction on the *S* trap of the former sufficient, nearly or quite, to break its seal, unless of unusual depth.
5. When the conditions are the same as in the last instance, the suction is not sufficient to cause the ball of Bower's trap to drop away from its bearing, nor is it sufficient entirely to remove the water from traps which, like Garland's and Cudell's, are closed by a valve bearing vertically downward upon its seal.
6. Brandeis's paragon trap showed no material superiority over the *S* trap. The water, under strong suction, was entirely removed from Nicholson's trap, but its mercury was not, and evidently could not be disturbed.
7. Mott's "anti-siphoning" Y branch of the soil-pipe possesses no material advantage over the ordinary Y branch.

Notwithstanding the fact that Mr. Waring insisted upon the accuracy of his experiments, conclusions differing from his were reached after another series of experiments by Philbrick and Bowditch, also conducted at the request of the National Board of Health. In these experiments it was found necessary to have a vent-hole in the trap, one inch and a half in diameter, with or without an opening in the top of the soil-pipe, in order to

prevent siphonage. The vent-hole or vent-pipe should be placed in the crown of the trap, and should exceed one inch and a half in diameter when the latter is of large caliber.

ARMY INTELLIGENCE.—Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 3, 1883, to February 10, 1883.—DE LOFFRE, AUGUSTUS A., Captain and Assistant Surgeon. Will be relieved from duty in the Department of the Missouri and report in person to the Commanding General, Department of the East, for assignment to duty. Par. 3, S. O. 26, A. G. O., January 31, 1883. —ELBREY, FREDERICK W., Captain and Assistant Surgeon. The leave of absence on surgeon's certificate of disability, granted July 21, 1882, is extended six months. Par. 5, S. O. 26, A. G. O., January 31, 1883. —TAYLOR, B. D., Captain and Assistant Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability. Par. 2, S. O. 13, Department of Texas, February 1, 1883. —TAYLOR, MARCUS E., Captain and Assistant Surgeon. So much of S. O. 20, A. G. O., January 24, 1883, as directs him to report in person to the Commanding General, Department of the East, is amended to direct him to report in person to the commanding officer, David's Island, New York Harbor, for duty at that station. Par. 2, S. O. 33, A. G. O., February 8, 1883.

Lectures and Addresses.

AN ABSTRACT OF THE PRESIDENT'S ADDRESS.

DELIVERED BEFORE THE NEW YORK ACADEMY OF MEDICINE
FEBRUARY 1, 1883.

BY FORDYCE BARKER, M. D., LL. D., ETC.

FELLOWS OF THE ACADEMY: I can not commence my remarks in the usual form by thanking you for again placing me in this position, for I had earnestly desired that the responsibility and labor involved in the effort to discharge the duties of the office which I have had the honor of holding by your kind suffrages might end with my second term of service. At a former meeting of the Academy, I stated my reasons for declining to be a candidate for renomination, which I hoped would be as conclusive in influencing the action of the Academy as they were in my own mind. I have always felt that a third term of service as President would, on general principles which I will not stop now to detail, be a doubtful and a dangerous experiment, not only for the incumbent, but for the interest and usefulness of the Academy. Furthermore, I felt that I did not owe the honor to professional merit or eminence, but that, on the part of the Academy, it was an expression of confidence that the duties of the office would be performed conscientiously, zealously, and faithfully. If the election was based on the principle of conferring honor, I know perfectly well that there are others much more deserving, or, if it were to be based on fitness and adaptation to best serve the interests of the Academy, I was equally sure that there were others who would bring to the place new strength and equal zeal and earnestness.

I can not deny that I had strong personal motives that influenced me in declining, because of the time and work which are required to perform the duties of the office well. But the general sentiment has been expressed to me so unequivocally, not only by individual solicitations by those who by their work have shown the greatest interest in the future of the Academy, but by the unanimity of your suffrages, that I feel the duty is plain for me to sacrifice personal feelings, and to yield personal convictions to the expressed judgment of the Academy.

Having relieved my mind by defining my position, I wish to relieve it still more by avowing not only my warm appreciation of this recent expression of your confidence, but my profound thanks for the aid and constant support which I have received, from the office-bearers as well as from the Fellows of the Academy, as a body and as individuals. It is a most grateful duty for me to acknowledge that I have never asked aid from a single Fellow, whether in the form of money, time, or mental work, that it has not been most cheerfully and promptly given, or some valid reasons, such as previous engagement, ill health, or necessary absence, been regretfully assigned. I think the character and high purposes of the Academy have been gloriously illustrated by the fact that in its past sixty-four sessions, to the best of

my belief, all have worked together most harmoniously, and not the slightest jar or irritation has occurred to disturb friendly personal relations. Naturally there must be difference of opinion in regard to matters of science and of practice: but the arguments in favor of one or the other side have been listened to with deferential politeness, and answered without temper or personal feeling. Questions of policy and expediency have been warmly discussed by those of decided convictions, but all have shown a readiness to yield to the expressed opinion of the vote of the majority, and no sting or rancor of feeling has been left behind. With this spirit we can count on a great future for the Academy.

The past and the future of the New York Academy of Medicine seem to me the most appropriate theme, when precedent has made it the duty of the Chair to take up the time which is usually occupied in a more important and profitable way in scientific work.

Of the one hundred and eighteen leading physicians and surgeons of this city who, thirty-six years ago, had the happy conception to unite in organizing this academy of medicine, there are now living but twenty-four, and some of these are still active working fellows, conspicuous by their never-flagging interest, their never-wavering devotion, their never-intermitting work in the interest of the Academy, and their almost uniform presence at its meetings.

Our library now contains over nineteen thousand volumes and between five and six thousand pamphlets, and I may say that it is daily increasing by the generous donations of friends. By the will of the late Dr. Robert A. Barry, and by that of the late Dr. Edward O. Beadle, it has received from the estate of the former 244 volumes, and from the estate of the latter 846 volumes, 668 pamphlets, and 537 numbers of medical journals. The generous gifts of our noble benefactor, Dr. Abram Du Bois, still continue to pour in upon us, and many medical publishers, both of this country and of England, have laid us under obligation by their kindness in sending us their new issues, a most liberal policy, as well as wise and remunerative from a business point of view. By the generous donation of a lady whose interest in the Academy and whose appreciation of its importance to the profession and the public continue unabated, by the noble and unexpected gift from the Northwestern Medical and Surgical Society, which it is to be hoped will prove an infectious example and precedent for other of the smaller societies of the city, and by individual subscriptions, the circulating department has been placed on a most efficient basis, and is working. I need not say most satisfactory to all interested, whom a little paragraph on our notice card clearly defines as those whose dues are paid. Our journal department is kept up to the former standard of excellence and attractiveness. I need not omit to state that the lady before referred to, who gave for this purpose, as you know, five hundred dollars two years since, authorized me to purchase, the past summer, any rare and valuable books that, in my judgment, such a library as this should possess; some such are already on the book and map shelves, and more will follow as soon as copies can be found for sale.

Passing to the personnel of the Academy, our faithful statistical secretary has reported at our meetings during the past four years the death of thirty-five of our Fellows, some of whom I will mention. Freeman J. Bumstead, James R. Wood, John W. Draper, George M. Beard, and others whose names do not at the moment recur to me, had attained such eminence by what they had done in the profession that they were well known in all parts of the world where there is a medical literature.

From our recording secretary I learn that in the past four years the Academy has elected and received one hundred and forty-seven new resident Fellows. Several have removed from the city, and, by their request, they have been elected non-resident Fellows. I have also the pleasure of stating that but two residents of this city have voluntarily resigned their fellowship.

I think the Academy has every reason to be satisfied with the amount of scientific work which has been done during this time, as sixty-six papers of unusual merit and importance have been read on subjects pertaining to pathology, general medicine and surgery, therapeutics, and the various special subjects of obstetrics, gynecology, dermatology, laryngology, otology, and ophthalmology, and the reading of these papers has been followed by able discussions, which have attracted notice and been largely reprinted both in American and in European journals. I can repeat what I have before said on a former occasion, that these discussions have been very valuable, because they have called out our ablest and best men, known to be experts in the special subjects of the papers read, and they have given the results of their careful study and large experience. We have rarely been compelled to listen to platitudes or crude statements of facts already well known to every intelligent and educated man. I can say that we have never been compelled to listen to the flippant loquacity of garrulous pretensions and assumptions, but we have had new reasoning, new statements of facts, new therapeutical suggestions, worthy of consideration and trial. It has been my aim to bring out papers which would in due proportion mark the progress of all departments of medicine, and thus in turn to secure the interest and aid in the improvement of all our Fellows. It is with great regret that I have been compelled to decline many papers which I am sure would have been listened to with great interest, and would have been most valuable, and brought out excellent discussions, simply because the time had been previously assigned to other papers. The number which have been offered have been far greater than the number of evenings which are devoted to this purpose. In a few instances papers have been recommended by one of our sections to be read before the Academy, and papers, too, that it would have been most desirable that the Academy should have the credit of. But the authors have preferred to bring them before the profession through some other medium rather than wait for an evening that had not been previously promised to other writers. In a few instances I have been compelled to decline papers whose merit and value I could not question, for the reason that the subject was one which would interest but a very limited number, and it would be impossible to bring out any dis-

cussion upon them. Such papers would find an appropriate place in, and would be valuable contributions for, some of our medical journals. These matters have often caused much embarrassment and disappointment, not only to the writers of papers, but to myself, and I am certain they would have caused it to the Academy if it had been aware of the facts. To prevent their repetition, I will earnestly beg all who are preparing papers for the Academy to inform me by note as long a time as possible before they wish to read them.

(To be concluded.)

ABSTRACT OF

THE CARTWRIGHT LECTURES ON THE RELATIONS OF MICRO-ORGANISMS TO DISEASE.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK,

BY WILLIAM T. BELFIELD, M. D.,
CHICAGO.

LECTURE I.

[The speaker was introduced by Dr. W. H. DRAPER, who remarked that the subject, "The Relations of Fungi to Disease," was one which certainly at the present time recommended itself to us as one of the most important for our consideration. It had so revolutionized our ideas of the pathology of many diseases, and our methods of treatment, that it was not possible to give the subject too much attention. The gentleman who had been appointed to deliver the Cartwright lectures on this occasion had had unusual facilities for acquiring practical experience in the study of the relation of the micro-parasites to disease; and he now took pleasure in introducing to the audience Dr. W. T. BELFIELD, of Chicago.]

Dr. BELFIELD opened his remarks by saying that in accepting this kind invitation to deliver the Cartwright Lectures he had, in compliance with the request of the Alumni Association, chosen this subject simply because of its intrinsic interest and importance, and also because there existed in the mind of the medical public in this country a divided opinion regarding it which seemed to him not to be warranted by the facts.

The speaker then referred to the inherent difficulties pertaining to the story of the subject under consideration; the necessity for extended facilities in pursuing investigations in the laboratory, the time and the expense necessarily involved, etc.—facts which, from the nature of our institutions, greatly limited original work in this direction in this country. In Europe, material aid was given original investigation of scientific subjects by the government. There had seemed to be a tendency on the part of the medical public in the United States to treat the subject under consideration as trivial or fanciful, and in general to ignore it. It was not his endeavor to present any original investigations, any theories or new views, but simply to state facts already established, and the deductions incident thereto, an effort which he was encouraged to undertake on account of some familiarity with the literature of the sub-

ject and a practical knowledge of the methods of manipulation.

Dr. Belfield then briefly referred to the history of the discovery and the study of the subject of bacteria, and said that even as early as 1675 bacteria had been observed. Fuchs had observed them in animals which had died in septic infection in 1848, and others had observed them in anthrax in 1849-'50. Pasteur, in his work on Fermentations, published in 1861, was the first to endeavor to establish a genetic relation between plants and diseases. At that time bacteria suddenly acquired an interest for the pathologist. The attention of the profession was drawn to the subject by the works of such authors as Meyerhofer, Cohn, Rindfleisch, Recklinghausen, and others, published from 1865 to 1867. Actuated by the investigations of Pasteur, Lister adopted certain methods in the treatment of disease, the clinical results of which led to a revolution in surgical methods, and gave new vigor to experimental pathology. He would consume no more time with an historical sketch, but would proceed at once with a review of the evidence upon which the subject rested.

The definition which Cohn had given of bacteria as early as 1875 was applicable at the present day, with slight modification: "Cells devoid of chlorophyll, spherical, oblong, or cylindrical, which reproduce themselves extensively by transverse division, and live either isolated or in families." To this was to be added the power of reproduction which was known to occur in several species. Many bacilli were also known to possess a thread-like projection from the extremity by means of which they were capable of motion in liquids. Nutrition and assimilation were carried on by a process of osmosis. This simplicity of structure had given rise to the discussion as to whether the bacilli belonged to the animal or to the vegetable kingdom. Our knowledge at present with regard to chemical reactions incident to their vital activity was very limited. An interesting fact respecting them was that the putrefaction of albuminous substances was incident to the vital activity of certain varieties. Their simplicity of organization explained their extensive distribution throughout nature. They were to be found in currents of air, in the dust carried by the wind, etc. Certain errors in manipulation and misinterpretations of facts, which were so liable to take place even with the greatest of care and most improved methods and facilities for investigation, would account for the serious mistake made by Pasteur and others in saying that bacteria were capable of spontaneous generation. There were some at the present day who were of opinion that they were capable of spontaneous generation, but, so far as evidence went, there was no reason to suppose that bacteria, like all other organisms, did not always proceed from pre-existing similar beings.

With regard to the nomenclature, unfortunately much confusion had arisen. Each investigator had been disposed to name each new variety according to his own individual fancy. The French school, following Pasteur, had in a loose manner made use of the terms vibrios, monads, torulaceae, etc. Dr. Belfield thought that Cohn's classification was the fittest to survive, but it also would have to undergo

some amendments. According to this system, the bacteria were distinguished by form as micrococci, micro-bacteria, bacilli, and spirilla. Each of these forms was then described.

The following was given as a definition of a bacterium: A mass of matter of definite shape and size, possessing or not possessing motion, of a certain chemical composition, having the power of growth and reproduction. No mass of matter could be said to be bacteria unless it possessed these qualities. Certain of these qualities, as said before, could be determined by examination under the microscope, and there were certain qualities which became manifest only under the action of reagents. For instance, aniline colors distinguished bacteria from such bodies as fibrin threads, fat granules, etc. But many of these qualities might exist in other bodies than bacteria, and lead to serious errors in deductions or statements of facts on the part of the observer. Instances of this kind were related. But even the experienced mycologist could not determine with absolute certainty that a given body was one of the bacteria except by cultivation outside of the body, demonstrating its reproductive power.

But with this arose practical difficulties which it was not always possible to overcome. Many objects might come in contact with the particle under examination which might also contain bacteria, and it was necessary to liberate the particle from all adherent organisms. We might, however, observe the strictest rules in this direction, and yet be unable to say positively that our precautions were altogether efficient. Dr. Belfield then selected cases from the literature of the subject, going to show how mistakes which had been made in this direction had led to very erroneous conclusions.

Two ways had been chiefly adopted in the isolation of bacteria from the blood or tissues of the animal for examination. First, by infiltration through some porous substance, as paper. But the imperfection of this method was evident. The method of cultivation could be divided into three groups, the first and the earliest being the worst, namely, in flasks or tubes containing the nutrient liquid. The errors liable to and which had grown out of this method were referred to at some length, and consisted chiefly in the extreme liability, at any of the transfers, to the admixture of foreign matter with the original. Should other living organisms become mixed with the bacteria being experimented upon, that which multiplied fastest, other things being equal, would, after a few transfers, be the only one remaining.

(*For illustration see slide.*)

CHAMBERS'S WEEKLY MEDICAL REVIEW.—Messrs. J. H. Chambers & Co., having purchased "The Chicago Medical Review," subsequently will hereafter issue it weekly, commencing at Chicago and St. Louis, under the name of "Chambers's Weekly Medical Review."

SOME WEEKS AGO a friend at Reading, England, had carelessly served a customer with a note instead of a soapbox. He returned the ballast as soon as the mistake was discovered, and sent him about the streets with the note about his person, and thus the daily drive. This is a rather novel way of punishing people who are not so called, but it was successful.—Times.

THE OPPORTUNITIES FOR THE STUDY OF MEDICINE IN NEW YORK CITY AFTER GRADUATION.

By D. B. St. JOHN ROOSA, M. D., LL. D.

IN my opinion, the best opportunities for the continuation of the study of medicine after graduation are to be found in hospitals. A large hospital is better than a small one, for the young practitioner should, if possible, see a large number of cases, and become rapidly saturated, as it were, with experience.

When private practice is entered upon, there will usually be ample time for the careful and deliberate study of a few cases. The number of large hospitals is, however, limited, even in New York. Besides, to enter one, the graduate must pass an examination, one that is competitive and usually much severer than that which gave him his degree.

But a few months as a resident in a small hospital afford a larger experience, and give more opportunities for practical work, than does time spent in any other way. Making a rude estimate, it may be said that there are from one hundred to one hundred and fifty places of all kinds, in hospitals large and small, general and special, that are to be filled annually in New York. When we remember that from four to five hundred men are graduated every spring in our city, we see that, at the best, only about one man in four can get a place. I fear, however, that some of these places go a begging in our city, although those in Bellevue, New York, Roosevelt, Charity, St. Luke's, and a few others, are eagerly sought after. Indeed, great and special preparation is made for passing the difficult examinations that are a prerequisite to getting one of these places. The young men who can not get these desirable places should by no means abandon the idea of securing a hospital position. The position of a clinical assistant or dresser, and finally of a House Physician or House Surgeon, in one of the smallest hospitals in New York, is, in my opinion, better able to prepare a man for active general practice, than even a lucrative place as an assistant or junior partner to a very busy medical man.

Senior partners are usually too busy to give much attention to instructing their associates, and it is just where the senior has become rusty that the young doctor, fresh from a college, needs to fix and assimilate his knowledge. The attending surgeons and physicians of hospitals are usually on frank and cordial terms with the house staff. They have none of the stiffness that they may assume as college professors, and he must be a dull scholar who does not get very valuable notes on the cases in the wards from these gentlemen.

When the young doctor has assimilated the knowledge he has obtained in a college by a hospital course, he then appreciates the intuitive skill of a busy practitioner. He can then learn by looking on, while in turn his own resources add something to the joint stock of knowledge and experience. But if the recent graduate has already been in a hospital, or if, from one circumstance or another, he can not

enter one as a member of the house staff, what can he do? Still I say come to New York, or stay in New York. If you have a decent stock of preparatory knowledge, a great deal of industry, good health, indomitable will, and about four hundred dollars in cash, or available funds, you will be a much better prepared general practitioner in six months than the average of those whom I have known after they have been five years in the profession without post-graduate training. A list of all the medical facilities of New York— one comprising the colleges, under-graduate and post-graduate, dispensaries, hospitals, general and special—should first be made. You will find all this in the New York "Medical Register," although not compactly arranged. Then, at the most, three or four subjects should be selected, to which three or six months may be devoted. Suppose, for example, general medicine, diseases of the skin, and gynecology are selected. In these departments you may have a weekly clinical lecture by such men as Flint, Delafield, Loomis, and Leaming, by paying the matriculation fee at their colleges. Then, for twenty dollars, you may have private instruction at the Polyclinic or Post-Graduate School, with visits to the hospital or dispensary with your private instructor. In skin disease you may get Socratic, practical instruction by Sturgis, Bulkley, Fox, and others. In gynecology, Dawson and Mundé will give you instruction in private classes, as a part of their post-graduate courses, while you may go to the weekly clinics at the under-graduate colleges, held by Thomas, Polk, and Lusk.

From Addis Emmet may be had an occasional opportunity to see operations at the Woman's Hospital on presentation of your card. Thus I might go on. Diseases of the throat and nose, of the eye and ear—all have their hospitals, to which the recent graduate is welcome, if he will hang up his hat and sit down and not saunter about as if he were some distinguished visitor who has just dropped in for a half-hour. Private courses in the ophthalmoscope, the laryngoscope, otoscope, and microscope, are given in connection with the post-graduate and under-graduate schools and at the hospitals, at hours and times that can be readily ascertained, and for fees that are very small. At many of the dispensaries and hospitals the attending surgeons are always short-handed for clinical clerks and assistants. A man who will attend regularly for some two or three weeks, so as to get acquainted with the staff, and who will attach himself to one physician or surgeon, will soon find himself well appreciated, and actually installed as an assistant, without examination, with unlimited opportunities for studying and observing the effects of treatment upon diseases. If post-mortem examinations be what is desired, at Bellevue rare opportunities are given, while Satterthwaite, Peabody, and others give private instruction in normal and pathological anatomy. The dissecting-rooms of the colleges are also open to graduates, during the winter and spring, on payment of the fees. In a month or so of regular visiting to the hospitals, a hard-working and modest man will make acquaintances in his particular department of study, who will give him an occasional opportunity to see private operations, and to go to the various societies, public and private, and hear the discussions. If the recent gradu-

ate has but a few weeks, the post-graduate school and poly-clinic will furnish all the opportunities he can use. If, however, he has months, these will not furnish all he can enjoy and profit by. The time has come, in our country, when even country villages and hamlets are critical as to the quality of their medical advice. A young man who has lounged about a physician's office for two or three summers, and spent but two short winter sessions at a medical college in a large city, will stand no chance by the side of one who has given three solid years to the earnest study of his profession in the college, and then added to that a number of months of practical work, where his responsibility is shared by an older head. The mere degree of M. D. has, fortunately, come to have slight significance. The medical schools of New York are becoming more and more accessible. When I say schools, I mean not only those strictly so called, but the hospitals and dispensaries, as well as the colleges. Directors and governors realize their responsibilities in the direction of opening them to students. Every year it becomes easier to get instruction. I would earnestly advise any recent graduate, no matter what branches of our science and art he wishes particularly to cultivate, to stop in New York before he goes to London, Paris, Berlin, or Vienna. From some experience in all of these cities, I think New York now offers to the English-speaking student advantages quite equal to those to be obtained in the old world. If, after graduation, a man can stay a year or two in hard work in New York, and then go abroad for a few additional months, he will, to my mind, have ideal opportunities. But better is it to stay here after graduation, if the two kinds of post-graduate instruction, that at home and that abroad, can not be obtained. There are master minds here as well as in the old world.

FROM GRADUATION TO PRACTICE.

By EDWARD BENNET BRONSON, M. D.,

PROFESSOR IN THE NEW YORK POLYCLINIC.

THE graduate in medicine beginning the practice of his profession directly after receiving his diploma finds himself in a position not unlike that of many a newly arrived traveler in foreign parts at his first essays to speak and understand the language of the country. The chances are that the traveler's sole knowledge of the tongue has been acquired in a limited series of "lessons" at home. With his own master he thought himself tolerably proficient, but abroad the inhabitants seem to talk the language in a different way; they have other voices; their expressions are peculiar; they make strange gestures; and utter their words so rapidly. The result is that, while the bewildered stranger catches here and there a familiar word or simple phrase, his diagnosis of the general meaning of what is said is apt to be very vague and confused.

The plight of the embryo practitioner is not much better. His mind is stored with excellent medical precepts, together with a fine assortment of correct prescriptions. He can discourse to his patient right learnedly, but, alas! like our traveler, he can talk better than he can understand. In his mental outfit are the keys to diagnoses of numberless diseases, but for the particular case in hand none of them ever

seem to fit. The cases which the young practitioner meets all appear to be anomalous ones. He recognizes as familiar certain features, certain symptoms, but then there are other symptoms that are entirely out of place and incongruous. The art of medical observation, the art of appreciating symptoms at their proper value, has not yet been acquired. The tyro is unduly concerned about "pathognomonic" symptoms, and is very prone to hasty generalizations—in a word, lacks practical experience. His three years' "curriculum" has afforded him more instruction than training, and it is only the combination of these two elements that makes a complete education. The training of practical observation and experience is necessary before his knowledge can profit him. Knowledge is power only when conjoined with wisdom. The studies of the medical student are so crowded with matters new and strange to him, they embrace subjects of such a varied character and so infinite in number, that the mind can afford but little activity to any faculty save that of memory. He emerges from the course with a vast collection of facts, but with very little individual judgment. His judgments are those of his professors; he scarcely dare make his prescriptions original, and his diagnoses are sure only when he meets the counterparts of cases he has been shown at the clinics. Alma Mater sets her young brood adrift to complete its evolution alone. She dubs the graduate "teacher of medicine," when yet he has the most to learn. Is it safe to trust this fledgling alone? He has his feathers, and much he may plume himself on them, but little he knows how they are to be used; he has yet to be taught to fly. The element of training is still lacking in his education. How is this to be obtained?

Without further instruction, the young graduate may adopt the independent course of beginning practice at once, trusting to time to remedy his defects. The objections to this course are that the experience, besides being acquired very slowly, is often warped by early prejudices that result from too partial observation, and impaired by careless methods of practice that are liable to become confirmed habits. The paucity of the material observed leads often to conclusions that a wider field and more friction with other observers would have shown plainly to be erroneous. Many succeed well in spite of these drawbacks; and, though it may be said of these practitioners, as of other self-made men, "It is better to be self-made than not made at all," it is none the less the duty of the physician to avail himself of every facility at his command to make his equipment for the intelligent practice of his art as thorough and complete as possible.

When the recent graduate has the opportunity of forming an association with an established physician of large practice, where his work is under the controlling influence of an older and more experienced head, his advantages are increased, but such an arrangement has also its disadvantages. The control which at first serves as a valuable check and guidance becomes in time a great hindrance to independence of opinion. The habit of referring every question to his superior checks the evolution of his own judgment, and tends to render him a mere reflection of the opinions of one man. Moreover, these opinions are not likely to be ac-

formly enlightened on all subjects. Every physician of position and experience has his strong points, but upon others his authority is less reliable. Indeed, few are free from more or less faulty prejudices. It is, perhaps, especially important that the young physician who assumes the relation of assistant or junior partner to an older practitioner should already have formed a broad mental ground-work of sound, catholic opinions.

With regard to the uses of the dispensary system in our large cities there is much to criticize. The material afforded for study is vast and of incalculable value, but, unfortunately, the manner in which it is generally used is most wasteful, and in too large a degree profitless. A young physician, often entirely inexperienced, is placed in charge of a class averaging from, say, ten to fifty or more new patients a day. There is a certain consciousness of official dignity in disposing of so many cases within the allotted hour. His patients are from an inferior class, that he looks upon with unavoidable disdain, and regards as simply so much food for science—and, were this food digested as it should be, more good would result both to science and to the patient. As it is, the material is bolted as rapidly as possible, occasionally pausing for a “snap” diagnosis of an “interesting case,” but with little appreciation of the advantages that are being squandered. While the conscience of the attending physician can ordinarily be trusted to deal in tolerably good faith with the patients he sees, he has neither time nor usually sufficient incentive to make such careful investigations as should be made. The physician is too isolated, too irresponsible, and slipshod work is too much the rule. The average dispensary class by no means affords that sort of training to the young graduate which he especially needs.

In a large hospital the system is vastly better. The “House” acts as the teacher of his assistants, and his work in turn is under the supervision of the attending physician. The members of the staff are in intimate association with one another, and their intercourse affords friction which keeps up enthusiasm in the work and tends to raise its standard. The experience gained by the *interne* of such a hospital is unexcelled by any method of medical training. But it has its limits. The term of service is a short one, and, though the cases observed embrace a wide range of diseases, there are many classes of affections which are rarely met with except in certain special institutions. Moreover, the conditions of the service often confine the *interne* to a certain department of the hospital, where he is exclusively concerned with a particular set of diseases. The arrangement is doubtless a wise one, and is attended with good results, so far as thoroughness in the work is concerned, but it nevertheless leaves the young physician at the end of his term of service still but partially prepared for all the exigencies of a general practice. The training he has received enables him to acquire what remains with comparative ease. In a good measure he has acquired the scientific habit, the art of weighing evidence as evinced by symptoms, the habit of recording observations, and, moreover, considerable expertness in making a diagnosis. His mental receptivity also is greatly increased. He can better digest new facts and estimate the value of new methods and theories. It is at this

period that the medical novice generally, when practicable, sought the advantages of foreign instruction.

Until recently there has been little or no provision in this country for the pursuit of such studies as are demanded at this period of the medical education. Abroad, at hospitals and polyclinics were courses especially designed for the practitioner—courses of short duration, several of which could be pursued together, and in which the matriculant was brought in contact with an abundance of classified material which he was enabled to study under the guidance of experienced specialists. The necessity of seeking these advantages abroad is, fortunately for the great majority of young physicians, becoming every year less. In the past few years much has been done to supply the requirements of practical clinical instruction which recent graduates demand. A number of classes in various special departments have been established in different institutions, and have uniformly been well attended. The two schools which have been opened in this city within the last few months, with the especial object of supplying the demand referred to, demonstrated the fact at once that such a demand was urgent. There is reason to believe that, in the future, schools of this character will form an important accessory of medical education. The plan of instruction that before had been followed in special institutions has in these schools been systematized and made more comprehensive. Many who seek instruction have already seen something of practice, and what they require is not didactic teaching but practical demonstration. They wish to see exemplified upon patients the proper methods of diagnosis and treatment by those whom long and special study has qualified to speak with a degree of authority.

Such are the facilities afforded the medical graduate to perfect his training for the practice of his profession. A word with regard to his *animus*—to the motives which should actuate him in this preparatory work. Unfortunately, in the pursuit of our profession, there are two important motives which are liable to conflict. One is scientific, the other commercial. But there need be no conflict; the two motives should be made coincident. For the practitioner an undue predominance of either is a loss. The physician wholly engrossed in the scientific aspects of his profession will have indifferent success as a practitioner. He may gain *κῶδος*, but few shekels. The doctor who practices with an eye single to his fee is false to his oath and false to his patients. In the early studies of the young physician, the commercial spirit is especially noxious. It belittles his professional aims and lowers the standard of his preparatory work. The desire for prosperity is a legitimate incentive so long as it does not predominate. The greater the interest in his work, the more likely that it will be effective and fruitful. But the prevailing motive should be the desire to acquire competence in his art; all else should be subordinate. A competence in his pocket will follow, and it will be seen how commercial aims may coincide with the legitimate requirements of science. But interest of some kind he must have that is live and active. The spirit that actuates him must be a thoroughly earnest one, or little will be accomplished. The most productive work is always that

which is directed to ends in which the mind takes an absorbing interest. This interest in the medical man may be greatly augmented by judicious attention to his natural predilections in the choice of particular departments of study.

After the elementary or fundamental part of his medical education is completed, the physician soon finds his natural tastes and aptitudes tending spontaneously toward certain special lines of medical investigation. By properly heeding these intimations he will not only add a spark of enthusiasm to his study, but, by giving his work a more definite direction, he will improve its quality. The attempt to cover the whole field of medicine uniformly will only result in superficiality. The aim should be, while striving to acquire proficiency in all departments, to attain excellence in one. The best work in medicine, without doubt, is being done in the "specialties." The specialist has a peculiar enthusiasm in his adopted department of study, and, moreover, the minuter his study the wider the field that expands before him, and the more it impels him onward. The farther he goes the better he appreciates the fact that the *consensus* of all the medical sciences is such that to excel in one branch of medicine he must also be proficient in all its sister branches. There are *artisans* in special medicine to whom the term "mere specialist" justly applies, but the specialist has no true title to the name who is not also a good physician.

It is not, however, the writer's intention to advise every young doctor to become a specialist. What he would urge is that each choose, sooner or later, some particular line of study in which he shall aim at an especially high standard of excellence, and from which, as a good point of departure, he can better attack the whole field. A wall intervenes between him and success. It is wiser to first effect a breach at some one point than to attempt to batter it all down at once. The fowler who singles out a particular bird in a flock will be surer of his game than he who makes a random shot at all. It is not designed that other departments of study shall be neglected, but that at some point there shall be a glow in his work; and the fire of enthusiasm once kindled will soon inflame the whole.

THE ARMY MEDICAL SERVICE.

By MORRIS J. ASCH, M. D.,

LATE BREVET-MAJOR, UNITED STATES ARMY.

To the young man who has finished his prescribed course of medical study, and is ready to take his place in the ranks of the workers in the profession, there must always elapse, except in a few fortunate instances, a certain number of years before he can make the seed sown during his years of studious toil bring forth pecuniary fruit. The widespread disinclination of the laity to trust the health of themselves or families to the "young doctor" is too painful a fact to advert to here, but is sufficiently common to make it often desirable that the youthful aspirant for medical success should tarry in Jericho until his beard be grown.

To such, or to those desiring to embark in a permanent career, the medical service of the United States army offers a most desirable opening. Composed of men carefully

selected from competing candidates, its medical corps compares favorably with that of any other nation, and to be a member of the body which has enriched medical literature with the works of an Otis and a Woodward is to possess an official recognition of professional capacity exceeding that conferred by the diploma of any of our colleges.

The medical corps of the United States army is composed of a Surgeon-general, with the rank of brigadier-general; an assistant surgeon-general, with the rank of colonel; a chief medical purveyor, with the rank of colonel; four surgeons, with the rank of colonel; ten surgeons, with the rank of lieutenant-colonel; fifty surgeons, with the rank of major, and one hundred and twenty-five assistant surgeons. On being appointed, the medical officer receives the commission of assistant surgeon, with the rank and pay of a first lieutenant mounted. After three years he becomes captain, with corresponding pay, which rank he holds until a vacancy promotes him to a full surgeny, with the rank of major. The grades of lieutenant-colonel and colonel are likewise attained by seniority, while the surgeon-general and assistant surgeon-general are chosen by selection from the whole corps.

The army of the United States being distributed in numerous small posts over a vast expanse of territory, its medical officers are usually without assistants. It therefore requires capable and self-reliant men, able to meet every emergency and assume any responsibility. The examination is necessarily rigid, and of the many applicants for appointment, but a small proportion are accepted, and these owe their commissions not to favoritism or political influence, but to their ability to meet the requirements of an impartial Board of Examiners, not vexatiously exacting, but scrupulously careful to insure that each successful candidate reaches the standard it has set. This standard is high, as it should be, and requires of the candidate, in addition to a thorough knowledge of his profession, a liberal education. Of two candidates possessing equal medical knowledge, preference would be given to the one who in addition gave evidence of the largest stock of acquirements. This is from no capricious desire to be exacting, but because the duties of the United States medical officer require him to possess qualifications of the highest order. Often called on to make reports on the capacity of new territories, a knowledge of the collateral sciences is indispensable. The examination is largely written, and includes a practical history of the knowledge of the candidate. The compensation in return for the required talent is liberal, if we compare it with the amount likely to be earned during the first years of professional life, while, as years roll on, if the pay is small as contrasted with the incomes of successful practitioners in large cities, we must remember that it is permanent, and that illness brings no diminution of it; while at the expiration of thirty years of service, or at sixty-two years of age, the officer is placed on the retired list with seventy-five per cent. of his full pay. On completing the course, the assistant surgeon receives the pay of a first lieutenant of cavalry, \$1,500 per annum; at the expiration of three years, \$2,000; a major receives \$2,400, a lieutenant-colonel \$3,000, and a colonel \$3,500. Every five years the officer receives an

addition of ten per cent. to his pay, which continues until the increase reaches forty per cent., when it becomes permanent. Besides this, he is furnished with quarters corresponding to his rank, and with forage for his horses, if in actual use.

On courts-martial and on occasions of ceremony the medical officer takes position with other officers of the army, according to his rank and grade.

The army of the United States being distributed to every part of the country, an officer may find infinite variety in his posts of duty. He may be stationed anywhere in the vast region—in the forts on the Atlantic or Pacific seaboard, on the plains of the South-west, or on the slopes of the rugged Rocky Mountain region. Sometimes his station may be at a division or department headquarters in one of the great cities, where he has an opportunity once more to compare himself with his professional brethren.

But, wherever the army surgeon may be stationed, he will be sure to gain a fund of information relative to the medical topography of the country that must prove invaluable, if he desires to continue his professional career in civil life. His position is always a pleasant one, for the medical corps is held in high esteem by the line officers of the army, and every opportunity is always afforded by commanding officers for the study of the flora and fauna of the country when the routine of daily duty gives sufficient leisure. The Medical Department is liberal in its provision of medical books and periodicals. Good microscopes and other means of scientific observation are furnished the different posts; and the military surgeon, though lonely, has no excuse for not being as well informed on the latest medical literature as his brother of the city. No better training in self-reliance and breadth of intellectual vision can be had than in our little army; the experience acquired there will stand in good stead when the officer returns to civil life. If he elects to remain in the service, an honorable position and an income sufficient for desires not too ambitious are insured to him.

POST-GRADUATE STUDY IN EUROPE.

By WILLIAM C. AYRES, M. D.

In advising a person who has just graduated at a school of medicine as to what would be the best course for him to pursue in a trip to Europe for the purpose of continuing his studies, what we have to say depends entirely upon the length of time which he intends to remain abroad. If there is no hurry, and two or three years can be taken for it, there are points which would be of the greatest value to know.

First of all, as to the expense. Germany is a cheap country to live in, and is also, I think, by far the best one to learn medicine in. It ought not to cost more than from forty to fifty dollars a month, with everything included. I know of a young man who lived in quite an expensive place in Germany, viz., Heidelberg, for twenty-five dollars a month for three years.

But before getting to Germany, and, in fact, before leaving this side, it is decidedly advisable to go to some

respectable broker, and have all the money you carry changed into English money, since this is at a premium all over Europe, and any one is glad to take it, whereas it is often not the case with other money.

Now as to the method of getting there. We all have our own ideas about transatlantic travel; but, after we have landed, one thing is well worth consideration. In England and on the Continent never take a *first-class* railroad ticket, for the second-class one gives you just as much comfort in traveling, and costs just two thirds as much as the first. It is an old saying in Germany that no one ever travels first-class except princes, green Americans, and fools.

Of course, in order to get as much out of a trip to the old country as possible, it is necessary that we should know the language of the people among whom we expect to reside. And, since Germany is by far the best place to study medicine in, we must either be already acquainted with the German language, or we must acquire a certain familiarity with it as soon as possible; and, in order to acquire this, there are many things to be observed. First of all, it must be firmly resolved not to speak any more English than is absolutely necessary; therefore, when once in Germany, avoid all American and English people, as they will certainly keep you from learning German.

Again, it is desirable to take lessons in German; but be particular to select a teacher who does not speak English; *and on all occasions speak German, whether you make mistakes or not.* It is really remarkable the facility with which the inhabitants learn to understand a foreigner when he tries to tell them something in their own language, even if he does not use a single word correctly. The theatre is also a fine place to get the ear accustomed to the sounds of the words, and especially since on the stage they speak the best German, and pronounce it most distinctly.

If one has some time to spend abroad, by all means he should go to some *small university town* like Heidelberg or Würzburg, Jena or Giessen, and start with *histology* and *pathology*, since in these places there are not so many novel things to distract, and also the professors and their assistants will devote more time to a single person; they are all more or less fond of Americans, especially if they find them to be diligent. As soon as they see that you wish to learn, they will go to any length to teach you. I remember that, when in Heidelberg, I had looked but a few times through a microscope and could hardly tell an air-bubble from a red blood corpuscle. Professor Arnold, the pathologist, was quite amused at first, but would sometimes sit for two hours by my side and pour pathology into me as if with a spoon. Spend the whole morning in the laboratory of pathology, for there you can also learn histology; after dinner, in the laboratory for physiology, and you will certainly be surprised at the amount of science you will absorb and the rapidity with which you will learn the language.

I had a friend who went to Jena and avoided all Americans for one year, then came to Heidelberg and passed his examination, obtaining the first grade in his Ph. D. in one year and a half. This I remark only to show how the language can be learned by avoiding all English-speaking people, throwing off false modesty, and speaking German

continually, whether you make mistakes or not, as before observed.

It would be well after the first semester (term) to attend the lectures and some of the clinics, but never miss a post-mortem when it can be helped, for they make them in a different way from what we do generally.

After a year and a half or two years, you may go to a larger town, and the selection will depend upon the special branch which you are desirous of paying attention to. Vienna is the best for obstetrics, diseases of women and children, and skin diseases, and also possibly for ophthalmology and otology, but for the latter branches Heidelberg is very fine. Moos, for the ear, is the very best man, since he does not have many students, and will devote the whole time to one man if necessary. Becker has the finest eye clinic in Europe, and is also very kind to students.

For surgery, Berlin, Vienna, or Munich is the best, but the last not so good as the others.

For pathology, no one is so renowned as Virchow in Berlin, but for this branch all of the universities are good. For microscopical pathology, the same may be said about the universities, but the preference might be given to Würzburg, Heidelberg, and Strassburg.

It is far more difficult to advise any one who only intends to spend six months or one year in Europe, but, nevertheless, as a general rule, what has been said about a longer period may be applied here also; with the exception that it will be almost impossible, in so short a time, to acquire enough of the language to understand a lecture or appreciate the fine points that any teacher may make. In this case I would spend at least half of the time, say six months (if one year is at disposal), in the laboratories of pathology above all, and then in those of physiology.

About these there can also be said a good deal which may be useful. For instance, if a person understands the language he has a great advantage, but if he does not, then I think that he should select some place where he can use English, as in Heidelberg.

Professor J. Arnold, who directs the laboratory of pathology, speaks English quite well, and is perfectly willing to speak it. His assistant, also, Professor Thoma, speaks English very fluently, and is fond of speaking it. So here is a rare chance.

Also in the laboratory of physiology is Professor Kühne, who speaks English, French, and German almost with the same fluency. Again, his assistant, Professor Ewald, has as good a command of our language as we ever find in a foreigner. Therefore, when there is only a year, Heidelberg is certainly the place in which to spend six months of it. There is another point to be considered, viz.: if it be possible, let this be in the spring and summer, for during those seasons it is one of the most beautiful places on earth, but the winter makes it very disagreeable.

After a time has been spent with the microscope in a smaller town, of course it is then advisable to go to the largest clinics to be had, where as much as possible can be seen. For this Berlin and Vienna are the places, but the latter has the preference over the former for many reasons.

Then, also, it will be winter, and that part of Europe is then much pleasanter than the latitude of Berlin. If you intend to spend the winter in Vienna, you may go directly from Heidelberg to Switzerland for the midsummer, when the universities are closed, and be near your winter home without loss of time or money.

If anyone is already more familiar with French than he is with German, and desires to acquaint himself with the French school of medicine rather than the German, he may go to France. In this case it would also be best to spend the first part of his time in one of the smaller towns. France, however, in not like Germany in having such a multitude of smaller places of learning; but as for the larger cities, we all know there is but one—Paris. In that city the hospital advantages are of the finest, and much time could be advantageously spent there. I am, however, inclined to think that the teaching in France is not quite so systematic and thorough as in Germany, since they are more apt to indulge in "glittering generalities" than to confine themselves to pure and absolute science. However, as a happy mean, where we find all the plodding perseverance of German system, and the fascinations of the French character, we may select Strassburg; there we find both a French and a German population, and may learn both the languages at the same time. But neither Strassburg German nor Strassburg French is of the purest.

A word about Great Britain. As to hospital advantages, there is no city in the world where they are greater than in London, but the same objections hold good for the teaching in England that we have found in the case of France. Pathology, however, can be studied to the greatest advantage in Edinburgh, whereas for physiology no place can be better than the laboratory of Professor Foster in Cambridge. The English surgeons are very brilliant, as we all know, and we may devote much time, if we wish, in England to the branches of surgery and physiology, and also much to pathology in Scotland.

The particular advantages of the larger cities we may say are: *Vienna*, obstetrics, diseases of women and children, surgery, skin diseases, ophthalmology, otology, and hospital practice; *Berlin*, pathology, surgery, chemistry, physiology, ophthalmology, and hospital practice; *Paris*, surgery, physiology, ophthalmology, and hospital practice; *London*, surgery and hospital practice; *Cambridge*, physiology; and *Edinburgh*, surgery and pathology.

Correspondence.

LETTER FROM WASHINGTON

WASHINGTON, February 1, 1882.

While making a tour of the National Academy of Medicine, I have had the opportunity of visiting the various laboratories, and have been struck by the high quality of the work. A number of the most important parts of the work have been seen, and the results are of the highest order.

already been reached of sufficient importance to suggest to me the idea of devoting this letter to some brief notes of the same.

I suppose that you have noticed the fact that the Public Health Association has adopted the naval "Museum of Hygiene" as its depository for specimens and models germane to its purposes, and that the American Medical Association took somewhat similar action at its last meeting. Possibly, too, you may have seen some of the photo-micrographs of organisms and crystalline bodies from the air, and of the bacterial forms found in the blood and secretions of certain forms of disease, and in potable waters, which have been published in the Surgeon-General's Reports, or have been distributed to the medical societies. It takes a long time, however, for the fruits of original research, carried on under official auspices, to struggle forth from the limbo of official reports into the open air of general professional knowledge; and it is therefore not strange that the visitor to the Naval Medical Building should find that it contains much that is both new and interesting.

The building is a large three-story brick house, or rather two houses thrown into one, standing on the south-east corner of Eighteenth and G Streets, scarcely more than a block away from the department. The second floor is occupied by the dispensary and the offices of the surgeons detailed to attend the families of the numerous officers stationed in this city. This department is well equipped with consulting- and waiting-rooms, a separate apartment for examinations with the laryngoscope, ophthalmoscope, and the like, and a very complete outfit of electro-therapeutic apparatus, including a large Fletcher's table, supplied by forty gravity cells, Byrne's and the Galvano-Faradic Company's batteries, and many appliances for special treatment, among which I notice a handsome Foster's gynecological table. Surgeon A. A. Hoehling and Passed Assistant-Surgeon T. M. Rixey comprise the medical staff, and, since the benefits of free medical treatment are shared by the families of all officers stationed in Washington, they can not be said to enjoy a sinecure.

In the back building are two large rooms on the second floor, one of which is devoted to microscopic research, and the other, by the use of light-tight shutters and a heliostat, is converted into a camera for photo-micrography. This work has grown from small beginnings during the last two years until now all of the photographic work called for, even to the preparation of the plates themselves, is done in the building and by naval medical officers. Beneath these rooms, in what were the kitchens of the house, is a good working chemical laboratory, sufficiently equipped for any ordinary analysis, and kept very constantly occupied. In the last Surgeon-General's Report, for example, it is stated that for the year preceding the number of analyses completed and reported on was 267, of which 172 were quantitative, 67 qualitative, and 28 partly quantitative, besides an extended series of analyses of atmospheric air; 150 microscopic specimens were mounted and preserved, and 82 photo-micrographs were made and printed. For the year just past I understand that the results are not only numerically greater, but cover a wider range, including studies of organisms found in sewer emanations, of ground air, of disease-germs as manifested in scarlatina, diphtheria, small-pox, typhoid fever, and anthrax, and several extended chemical analyses for other bureaus than that of medicine and surgery. The laboratory, microscopic, and photographic work are at present done by Passed Assistant-Surgeon Griffith, under the general supervision of Medical Director J. M. Browne, who is in charge of the museum with its subordinate branches.

The first of these which the visitor meets with, on entering what were the reception parlors of the house in its hospitable days, is the library, occupied also as an office by Dr. Browne and his two assistants, Drs. Streets and Henneberger. Here are

eighty periodicals, conveniently arranged in a case which stands in the middle of an enormous reading- and writing-table, and alcove cases containing between three and four thousand volumes. The library is loaded down by a surprisingly small amount of dead weight in the way of useless or unavailable books. It is particularly strong in fine editions of the older classics, and of full sets of standard periodicals, most of which have been added during the last two years. Upon the walls are plans and elevations of famous hospitals, among which I recall examples at Leipzig, Lima, and the British hospital-ship *Victor Emmanuel*, at Hong-Kong. In cases are set up complete sets of the apparatus for physiological research described and figured in Burdon Sanderson's "Hand-Book for the Physiological Laboratory," a Browning's model spectroscope, model electric lamp, etc., etc. Upon a stand in the library proper is a fine model of the Hicks United States Army General Hospital, presented by the Army Medical Museum. Out of doors, upon a large wooden platform, are set up specimens of every form and size of drain-tile, presented by the National Museum. In the long room once used as a ball-room, beyond the library, things were in a less orderly condition at the time of my visit. One set of workmen was at work upon the frames for exhibition of specimens, which are modeled after those adopted by the National Museum; another set was completing water and sewer connections for a very full exhibition of the different systems of house sewerage and drainage, including traps, soil-pipes, closets, ventilating-pipes, and all the mysterious *armamentarium* of the plumber. In one corner stands a sectional model of one of the burial-caskets sent to the Lena River for the remains of poor De Long's party; in another there are models of the various ambulances, wheeled stretchers, and other military devices for the transportation of the wounded, presented by the Medical Department of the Army. Slung up against the ceiling are various forms of cot for lowering wounded men from the spar deck during engagements at sea. In the middle of the room is an enormous sectional model of a hospital-ship, showing all the decks and the hold; in another place a model of a ship's forecastle, showing the sick-bay. The walls are well covered with framed sectional drawings of drainage systems, specimens of wall coverings, fabrics useful in the construction of hospitals, and plans of hospitals and hospital-ships.

Without going further with what threatens to degenerate into a catalogue of specimens, I may say that this young museum, scarcely two months advanced from its beginning, is already outgrowing its available space, and is receiving accessions at a rate which shows how fully all manufacturers and students interested in its purposes appreciate the advantages of such an exhibition. Even in its present stage, I know of no place in this country where an inquiring medical man can get so full and intelligible information as to the various systems of drainage, for example, in so compact and accessible a form.

Another evidence of the activity of the medical corps of the navy is to be found in the Naval Medical Society, which meets on the first Thursday in each month in the library, and which has just published the first number of its Transactions. I have requested that a copy be sent to you, the subject of discussion being one of great interest to all persons in the military service—viz., The Line of Duty, or, in other words, the responsibility of the medical officer in the determination of claims to pension.

Passing to another part of the city, the inquiring visitor finds that one of the furthest advanced and most complete exhibits in the new National Museum is the *materia medica* collection, under the charge of Surgeon James M. Flint, United States navy, detailed for the purpose by the Surgeon-General. Here are to be found the *materia medica* of every pharmacopœia on earth, including, for example, those of China and Siam. Not

only the preparations are shown, but the original root, bark, or leaf-drawings and pressed specimens of the characteristic parts of plants, mineral waters, even objects used superstitiously, as amulets and charms, such as horse-chestnuts against rheumatism, and the like. Connected with the exhibit proper there are in course of preparation careful collations of the synonymy of different pharmacopœias, of the differences between compounds of similar names in the official as well as the official preparations of different countries, and a series of descriptive labels, which are truly marvels of accurate and laborious condensation. One striking feature of this exhibit consists in the display of mineral waters. Around a litre-jar of Friedrichs-hall water, for example, are grouped a number of tall phials containing, each, one of the salts which make up the mineral water, and the exact quantity of the salt contained in one litre of the water. The bottles are all of uniform height, but of varying diameter, arranged in cases of the standard pattern, which run all through the museum. The educational value of such a collection, and of its accompanying publications, not only to medical men who have to practice in foreign countries, but to students and lecturers on materia medica as well, must be apparent without argument.

It would seem that, with the advantages of a library well stocked with periodicals and books of reference, of laboratory facilities, the apparatus at the dispensary, the National Museum exhibits, and a medical society of its own, the medical corps of the navy ought to be a body in which its members should take pride, and which should present unusual inducements to successful graduates who are seeking opportunities for advancement. There is, however, unfortunately, another side to the shield, and, while the corps is undeniably doing something tangible for the advancement of science within its own lines of action, it seems to be unable to do much for itself. Just at this time there is a particularly widespread sense of dissatisfaction among medical officers, growing out of the evidence afforded by recent debates in Congress that a large branch of the service to which they belong desires strongly to reduce their official standing and to diminish their pay. It has been seriously proposed in Congress to muster out of the service the two highest grades of medical officers, without compensation for the many years spent in the lower grades, or for the peculiar character of the service required of them, which has deprived them of the opportunities for establishing the connections on shore necessary to success in any business. It has been proposed also to dispense with a medical corps altogether, shipping a surgeon for the cruise, as is done in the merchant service, and discharging him at its termination. The proposition to reduce the pay of staff officers was defeated by but a narrow majority, and is very likely to come up again hereafter.

Considering these facts, and, furthermore, that, for some years after entering, the assistant surgeon is now compelled to live in the steerage, without separate quarters, or opportunities for study, I doubt whether it is altogether judicious to urge the few graduates of each year who are competent to pass the naval medical examinations to compete for positions in a service in which the duties are onerous, the official rank doubtful at best, and the rewards not only meager, but likely to be withheld just at the time when advancing years have exhausted the energies of youth and the capacity for beginning life over again. Every one who is interested in medical education must look with regret upon any deterioration in the value of the few rewards which now serve to stimulate the zeal and enthusiasm of students to special efforts, since we can not yet boast that the standard of the "pass" examination is as high as it might and should be. But, although the impulse to lend a helping hand to a worthy but failing body of our brethren is doubtless as strong

in the profession as it was twelve or fourteen years ago, when the medical societies throughout the country spoke to this text with no uncertain sound, I doubt whether something more than assistance from without will not be necessary in this case. If neither the navy as a whole, nor Congress which controls it, can see the advantage of attracting and retaining within its body the best medical ability obtainable, there certainly seems to the average outsider to be something radically "crass" in the body itself; a sort of mental strabismus that must be cured by operation before anything like correct vision can be hoped for.

If, however, there be still among your younger readers those who, rather than bear the ills they have, will fly to others that they know not of, I will say that I learned, on my visit of inquiry to the Surgeon-General's office, that a medical examining board would meet at Philadelphia on the 1st of March, and that there were now two vacancies in the medical corps of the navy, the last appropriation bill having reduced the number by ten. Permits to appear before the board are easily obtained, the success of the candidate depending much more upon the sort of examination he passes than upon the kind of introduction he brings with him. By the act of 1877 the rule has been so far changed that the rank of the successful candidate is permanently fixed by his first examination, and is no longer, as heretofore, subject to change by his success when examined for his first promotion. Under the rule which had prevailed for some thirty or forty years prior to this act, every assistant surgeon had a chance to better himself, relatively to others of his year, by diligent study during his service in that grade, and the arrangement certainly seems to have been a judicious one, as tending to stimulate continued industry after the first examination. As it is now, I should say that the candidate who knows some medical officer, and can so get an idea of the scope and character of the examination, will have a decided advantage over him who goes up without knowing anything about what is before him.

But I dare say you have had quite enough of the navy for one occasion, and I have left myself no room for anything else, the subject being of especial interest to doctors here at this time for reasons already touched upon.

LETTER FROM PHILADELPHIA.

PHILADELPHIA, Feb. 24, 1883.

I HARDLY KNOW what to reply to your queries as to the chances for success of a young graduate in this city. I suppose that it is much like other large places in being superabundantly supplied with medical men, still, for the right sort of man, there is always room. There are two chief plans adopted by most aspirants to fame and practice here, which, with certain subsidiary means necessarily varying with the individual and his surroundings, usually prove more or less successful. Probably the easiest is first to secure a position as interne in one of our hospitals. Now, as we have five large ones where these positions are filled solely on the recommendation of the medical board after examination, two still larger—the chief surgical hospitals—where personal influence alone avails, and a third where meritorious examination nominally, but political influence really, alone secures appointment, it must be hard luck, indeed, if the persevering aspirant does not "get ahead." As the chances vary from two to a dozen or more, very advantages, many of terms, etc., no man need fail of an appointment, if he will wait long enough. His time as interne having expired, he must next settle near his old hospital—of passing to that of our rapidly growing neighborhood—where, as soon as he can, an assistant physicianship or surgeons'hip at his hospital, and a moderate but

self with some member of the staff, whereby odd patients, night cases, etherizations, and "sitting-up cases"—at twenty-five dollars a night—may fall to his lot. The more scientific plan is to do everything as heretofore described except the choice of locality, which must be decidedly "swell." The aspirant must then proceed to write himself into practice, attach himself as clinical assistant, demonstrator of anatomy, surgery, histology, or something of that sort, in one of our three medical schools; or, after being in Europe for a few months, come back to set all his old instructors right. This may seem jest, but I mean it for earnest, having seen it done over and over again. If a really meritorious man, he is soon taken up by some of our prominent men, who get him to work for them as clinical clerk, or in some other capacity, either paying him a small salary or sending him practice. This is the history of many of our rising men. I should have added, of course, that he must join one of our many societies, preferably either the County Society or the Pathological, or both, where, by actively debating and reading papers, I can recall a dozen solid reputations made within a few years. Nothing beyond residence in the county for one year, and the recommendation of three members, need precede election in the former, while the same requisites, less the residence, will render any one eligible for election to the latter.

Most ambitious men either take some of the numerous private post-graduate courses, or the excellent ones at the University, or of the new Post-Graduate School here. Quizzing, reporting lectures, writing reviews, acting as temporary traveling attendants upon fashionable patients, enable some of the more fortunate aspirants to keep the wolf from the door. There are innumerable out-patient departments here which occupy many men; and the old Philadelphia Dispensary, with its various district physicians, who attend the patients at their homes, has been the means in the past of starting some of our best men in a paying practice. As copyists, amanuenses, proof-readers, etc., certain men manage to eke out their means to no contemptible extent.

To any man who desires to do good scientific work, to lay the foundation of, and indeed build up, a solid scientific reputation, I know of no place better to come to than this, believing, as I do, that nowhere in this country can he find better or as good facilities. Unless, however, he has means or backing, or, in lieu of these, indomitable pluck, this overcrowded city is not the place to settle in. With any of the above-named qualifications, preferably both of the former, he will probably succeed by the means I have pointed out, although it will take, in most instances, a long time. If I had my choice, I should certainly advise a young man rather to settle in one of our growing smaller cities, such as Chester.

I omitted saying that, although a few years ago almost unknown, now the older practitioners are beginning to have regular partners in the shape of assistants, their offices being together, or, at least, they practically have such, by invariably sending their patients to certain of their *protégés*, and directing them—the patients—to send to a certain physician in an emergency, or after a certain hour of the day. This opens up other chances for a certain number of superior men.

And now I will close my rather rambling letter with the promise to try to give in my next a true account of the pros and cons of the recent "body-snatching" affair, which as yet remains unsettled. Only one side has been heard, while Dr. Forbes has received, to put it mildly, scant justice at the hands of both the medical as well as the secular press. This may seem like promising something which can hardly be called news, but I think that the legal aspects of the matter will hardly be settled before I write again, and I wish to set your readers right about the Anatomy Act and the supply of material here, con-

cerning both of which you seem to be under some misapprehension, judging from some paragraphs that I read in one of your January numbers.

LETTER FROM BALTIMORE.

BALTIMORE, January 31, 1883.

WITHIN the past five years Baltimore has made marked progress in the facilities which she offers to the medical student in the direction of a higher medical education. From a position subordinate to New York, Philadelphia, and Boston as a medical center, she now fairly rivals these important medical communities, and it is only a question of a few years when the advantage may be claimed in her favor. There are at present four medical schools in active operation here, and the fifth, the Medical Department of the Johns Hopkins University, will most probably be at work within the next five years. These schools are the University of Maryland, Medical Department, one of the oldest and most reputable institutions in this country; the College of Physicians and Surgeons, a vigorous and wide-awake school of some ten years' growth; the Baltimore Medical College, an institution as yet in its first dentition; and the Woman's Medical College, recently organized, but vigorous and progressive. Independent of the strictly medical schools, there are two dental institutions and the College of Pharmacy. They have matriculated at their several schools during the present winter 590 medical students, about 103 dental students, and 87 students of pharmacy, or a total of 780, engaged in the study of medicine and its cognate branches. These large classes of students are mainly drawn to this city by the excellent opportunities which they have presented to them for didactic and clinical instruction. It may be fairly claimed that the gentlemen engaged in teaching in the medical schools of this city are as able and conscientious teachers as fill similar chairs in the various medical schools throughout the country. The course of instruction is about as thorough and satisfactory as that offered by similar unendowed medical schools elsewhere. Attached to the two leading schools are well-conducted hospitals, which offer excellent clinical advantages, and, in connection with large outdoor departments, furnish a variety and abundance of clinical material, which is fully and carefully utilized. This fact has added materially to the strength of medical teaching here. Clinical instruction is appreciated and insisted upon, and the material is presented to the student in its most practical form.

To the graduate in medicine, Baltimore presents numerous advantages which in the near future will invite a large number of men seeking a high medical education. To the graduates of the city schools the positions of resident and interne are available at the University Hospital, City Hospital, and Bay View Asylum (City Almshouse), while graduates from other cities may take advantage of the laboratories of the Johns Hopkins University for special work in chemistry, biology, and physiology. The graduate may pursue any special line of study with advantage. He is admitted to the daily clinics at the several schools where special instruction is given, or, if disposed, may visit such excellent institutions as the Presbyterian Charity Eye and Ear Hospital, the Baltimore Eye, Ear, and Throat Charity Hospital, the Union Protestant and Church Home Infirmary, and similar hospitals.

The objective point of interest to the student in search of a higher education centers at the Johns Hopkins University. No institution in this country is more courteous and considerate in its regard for the student than the Hopkins, and no institution is more admirable in its system of instruction, in its facilities for imparting knowledge, and in its purposes, than the one mentioned. The chemical, physiological, and biological departments of the Hopkins have been organized with a thoroughness and

comprehensiveness unsurpassed by any school in the old world, and without a rival in the new.

The original work carried on in these departments is marked for its accuracy and finish, and for the valuable additions it has made to scientific knowledge. The student of the Hopkins enjoys great freedom and latitude in his researches, and valuable aid in his efforts. He has placed at his command an abundance of material for experimentation, the use of the most recent and improved appliances, and such careful instruction that he can rarely fail to produce something original and valuable. The vast resources of these laboratories are open to the student for a comparatively trivial sum. Nowhere can so much be obtained for so little outlay. To one who shows marked fitness for original research and study there is open to successful effort the position of Fellow with its annuity of five hundred dollars, or the Ph. D. with its implied preferment.

The work at the Hopkins in higher medical education has had a salutary effect upon medical interests in Baltimore. The outlook here is most encouraging, and the day is not far distant when the entire profession will experience the benefit of this large and liberal culture in scientific thought and effort.

Now almost completed is the Johns Hopkins Hospital, with its ample endowment, admirable location, and superior accommodations for the sick. This hospital will be opened to patients within two years' time. It will have a capacity of about three hundred beds, yet, to accommodate this number of patients, its wards and administration buildings cover an area of eleven acres of ground. It is built upon the pavilion plan, and after the most recent and approved system of hospital construction. When completed, it will be a palatial home for the sick, wherein will be found in rich abundance all that art and science can contribute to the alleviation of human suffering. The Hopkins Hospital will offer the very best advantages for clinical and pathological instruction, and, when associated with that system of training to be inaugurated by the Hopkins School of Medicine, medical education in Baltimore will receive an impress of thoroughness and reliability of the highest order. The advanced student will here find such opportunities for thorough training as will meet his far reaching wants. The profession in Baltimore contemplates with pride the early inauguration of this higher work in medical education. Already it has felt the first stimulus of the new system, and insensibly it is molding itself to the changed relations which these associations bring. There has been a decided revival of activity and effort in scientific work. As a result, medical interests here are more aroused, organization is more thorough, the professional pulse beats with quicker and stronger impulse. Less than a decade ago there were but two feeble medical societies in the city. To-day four active and growing medical associations occupy the field, and contribute a useful part in advancing the claims of legitimate medicine. Any member of the profession in good standing and a resident of the city is eligible to membership in any or all of these societies. The Clinical Society, with a present membership of over 140, admits any physician residing in the State, while the Academy of Medicine levies a special tax in the form of an acceptable thesis upon all applicants. The recent graduate in medicine can obtain admission to any one or to all of these societies, and he may reap a decided advantage from the very practical and able discussions which prevail.

A movement is now on foot to establish a post-graduate school and a polyclinic in Baltimore. It is claimed that the promoters of this scheme that such an institution will meet a real need in this medical community, and that it will at once secure a large complement of students. The gentlemen active in this movement seem to be in earnest, and it is possible that success

will ultimately reward their efforts. It is, however, maintained by others that no real need exists here for this character of post-graduate instruction. It is held that the Hopkins school, with its splendid facilities for special work, will present such advantages to students as will impoverish smaller interest-seeking to cultivate the clinical field. Several years must elapse before the Hopkins school will be able to offer clinical instruction, and, in the mean time, the polyclinic may receive a permanent establishment.

The close proximity of Baltimore to Washington is of decided advantage to the student of advanced medicine. Within an hour's time he may be under the roof of the Library of the Surgeon-General's Office, or the Library of the Medical Museum or Smithsonian Institution. The vast collection of scientific literature and material at the Capital is very nearly as accessible to the resident of Baltimore as to one living in the District. This fact, taken in connection with the general advantages which this city is beginning to offer to students, will add materially to the influences already at work in favor of advanced medical instruction.

LETTER FROM BOSTON.

Boston, February 14, 1883.

THE establishment and promising success of the Post-Graduate School, and the Polyclinic Courses of Instruction, in New York, is a matter of general interest throughout the country, and may lead to inquiry as to what similar advantages exist in our own neighborhood. Eleven years ago, Harvard made the first change in medical instruction by establishing the graded, or, as it was called, the "new system" of medical education, and, although it was predicted that it would be a failure, the result has been the contrary.

When this had been proved a success, the graduates' courses were established—in surgery, clinical medicine, obstetrics, and the various special branches. The fees were fixed at a comparatively low rate, and many new graduates and older practitioners availed themselves of these advantages.

One inducement was that graduates from other colleges, attending a full year's course and passing a satisfactory examination, could obtain the Harvard degree, and a number, who from various causes were unable to attend a full three years' course at Harvard, graduated at provincial institutions, and finished off in this graduates' course. The system has continued in force, and, with a large number of professors and instructors, Harvard thus has an under-graduate and post graduate course under one management. As they are arranged, one can take the full course, or confine himself to one subject.

Instruction in general medicine and surgery is given at the Massachusetts General and the City Hospital, and at the Boston Dispensary.

Histology, physiology, medical chemistry, and pathological anatomy may be studied in the various laboratories, under skillful instructors, while other special branches are distributed as follows: Clinical obstetrics finds its material in the Boston Lying-in Hospital, and in the districts of the Boston Dispensary; many of the confinement cases are attended by young women, the care of the delivery being entrusted to the student, and professor of obstetrics, who sends a female doctor to attend the patients, and, as a degree is not given till a student has attended three cases of confinement, and made written reports thereon, it is a decided advantage to the student to attend to meet the demand.

The course in clinical medicine is conducted by Assistant Professor W. L. Richardson. When possible, operations are performed at the Lying-in Hospital, in presence of a number of

the class. At the school all the operations are demonstrated upon the cadaver.

Those desirous of paying attention to dermatology and laryngoscopy can be accommodated at the out-patient departments of the hospital, and, also, special students in these studies may obtain private instruction from the same sources, and at the dispensary. Ten years ago a student at Harvard rarely saw a uterine examination made; now the study of gynecology can be advantageously pursued—the clinics of the dispensary and the Free Hospital for Women being the sources from which the material is furnished; and, in addition to these, the Assistant Professor of Gynecology, Dr. W. H. Baker, intends to establish a clinic at the Medical School, when the new building is occupied.

A large city always gives good opportunities for the study of venereal diseases. Material for this class of cases is found not only in the out-patient departments of the hospitals, and at the dispensary, where there is a special clinic for such patients, but also at the Naval and the Marine hospitals at Chelsea.

Diseases of the eye and ear may be studied to advantage at the Massachusetts Charitable Eye and Ear Infirmary, at the Boston City Hospital, and at the out-patient department of the Massachusetts General.

Six years ago the office of coroner was abolished in this State, and medical examiners were appointed in their place, and the duties of the old office were divided, the examiners attending to the medical part, and a trial justice looking after the legalities.

There are two medical examiners for Suffolk County, both of whom are instructors at the Medical School; and, as many autopsies are made and demonstrated by them in the presence of the class, it will be seen that the opportunities for the study of forensic medicine are good.

Thus, all the special and general branches of medicine may be pursued by any physician in the graduates' course.

In New York, all the house officers in the various hospitals are, I believe, graduates; here, on the contrary, no one who has received a degree is allowed to apply as an interne, save in one exception, to be mentioned further on.

At the Massachusetts General Hospital, junior students are appointed to serve as assistants in the various out-patient departments, while senior students are appointed to serve as House Physicians or House Surgeons, they being called medical or surgical house pupils.

At the City Hospital, a competitive examination is held every six months, and six house officers are appointed, for a service of eighteen months—six months as externes, after which they are medical, surgical, or ophthalmic internes, as the case may be. The service is so arranged that a man has a chance of serving in each department.

In the Lying-in Hospital the term of service is six months—three months as junior, and then three months as senior House Physician, and under-graduates are alone accepted.

At the Children's Hospital there are three appointments—two internes, a medical and surgical, and one externe.

At the Carney Hospital two house officers are appointed, but their being graduates is not considered an obstacle. One serves as House Physician, the other as House Surgeon.

In the Massachusetts General and the city hospitals the internes are allowed to graduate before their term of service has ended.

So much for the direct neighborhood of Boston. The only other hospitals in New England connected with medical education are those at Portland, Maine, and Burlington, Vermont. At the former, two house officers are appointed each year—one medical and one surgical—and those selected for the office have generally taken the course at Bowdoin and the Portland School

for Medical Instruction. At the latter, in the Mary Fletcher Hospital, two are also appointed. Here the selection is made from those who have completed their studies at the medical department of the University of Vermont. In both instances under-graduates are selected.

The Rhode Island Hospital, at Providence, is not connected with any medical school. Three assistants are appointed each year, and the service is both pleasant and instructive.

Concerning appointments upon the visiting staff of our hospitals there is nothing to be said that will give encouragement to a young graduate coming to Boston. The opportunities are few and the applicants are numerous, and one who has not served as an interne stands very little chance. The motto is, "The best man for the place"; but the "best man" generally proves to be the one who has the most influence.

Some one once asked Governor Dix what his rule was in appointing professional men to official positions; he replied: "I sift the candidates down to two, and, if their professional standing is equal, I give it to the one who has the most political influence." I think a similar rule applies to hospital appointments here.

To a man who wishes to make a special study of the diseases of the eye and ear, I know of no place better than the Massachusetts Charitable Eye and Ear Infirmary. The clinic is large, and the staff able; and, besides one interne, there are externe appointments, and a beginner, while waiting for practice, can spend his mornings at the infirmary, and either drop the appointment as patients come to his office, or, if he means to take up the specialty, continue till a vacancy in the staff makes room for his promotion.

At the Boston Dispensary any one can apply for a district, a position which has a salary of \$200 a year; and, even when one can not obtain the appointment, he can get the chance to act as substitute in a district, or a room, and thus be kept busy till his own time comes. Societies with us are sufficiently numerous.

The State is divided into districts, corresponding in general to the various counties, and the Massachusetts Medical Society consists of the district societies, the appropriate one of which every regular physician is expected to join. To obtain membership, one has to pass an examination more or less stringent, according to the Board of Censors who examine. In the Suffolk district, which consists of the city of Boston proper, the examination is partly written, partly oral, and is comparatively severe, while in some districts it is treated too much as a matter of form.

In so large a society as the Suffolk district, the regular meetings, which now occur bi-monthly, are too crowded for comfort, so various sections are formed—of clinical medicine, surgery, obstetrics, etc.—meeting at shorter intervals, and members attend those that interest them the most, and in this manner much earnest work is accomplished.

The Boston Society of Medical Observation was founded through the endeavors of Dr. H. I. Bowditch, now the Nestor of the society, after the manner of the Observation Society of Paris. The meetings are held twice a month, except during the summer, and each member in turn reports a case, which serves as the basis for discussion and criticism, in which it is intended that the utmost frankness and courteous freedom should prevail. The number of "associate" members who hold the meetings is not limited. A part of their assessments goes to aid in the supply of medical journals, which circulate among forty so-called "active" members, who pay a higher assessment. All the leading American, English, French, and German medical periodicals are taken, and pass weekly from member to member in turn, after which they are deposited in the medical library. In order to become a member, one must be a member of the Massachusetts Medical Society, and have been in practice a year,

NEW YORK, SATURDAY, FEBRUARY 24, 1883.

THE YOUNG GRADUATE AND HIS NEEDS.

It is the well-known custom of several medical journals to devote one of their early autumn numbers each year to the special needs of medical students and of such as intend to enter upon the study of medicine, and thereby much good is doubtless accomplished. It has seemed to us, however, that those who have just ceased to be medical students (in the ordinary acceptance of the term, although it is to be hoped that they will never cease to be students in reality) stand quite as much in need of all possible information bearing upon their prospects, and the paths that are open before them, as they did when they first entered upon their course of medical study. Indeed, it would be difficult to name a position in life where more depends upon the way one shapes his acts than in that occupied by the man who finds himself the possessor of a diploma in medicine—that "license to study," as it was humorously termed by the late Professor Robert Watts. It is on this account that we have taken pains to prepare this "College Commencement Number" of the journal, that name being given to it because this is about the time of the year at which the annual commencement takes place in most of the medical colleges of this country.

It is not our purpose in this article to lecture the young graduate in regard to what his particular necessities are, or how they are to be met; we refer him, as to those matters, to the contributed articles that it has been our good fortune to obtain for this number of the journal. It is rather our aim to encourage him, and to assist him to react from the rude shocks that will be put upon him by the world into which he launches forth. He will be told over and over again, for instance, that, however sound and comprehensive his theoretical knowledge may be, he has still to be clothed with the armor of practical experience before he can become a safe man to depend upon. Of course, there is a great deal of force in this, and the young physician will readily confess it to himself; but let him not carry his self-criticism so far as to think that the greater part of the work is yet before him, and that he has accomplished comparatively nothing. Such is not the case by any means; he has not achieved all, but he has mastered the greater part, not the lesser. There can be no more egregious error than to esteem mere experience above well-arranged theoretical knowledge. Let two men roam the woods in quest of wild flowers—one of them an illiterate rustic, but familiar with every plant that grows in those parts; the other a man who has studied botany systematically, but has never before been beyond the sight of bricks and mortar. Straightway they come upon a flower that rouses the latter's curiosity. He asks its name. His companion, with an air of

superiority, glibly ejaculates the local name of the plant—but what a name! In the great majority of instances it is utterly meaningless, and the fellow who gives it with so much importance can tell little or nothing else about the plant; whereas the man of science, although so inexperienced as never to have beheld the thing before, will, in the course of a few minutes, roll out so much information about it that the rustic will speedily come to the conclusion that he has been quizzed. So it is in all departments of knowledge, medicine as well as anything else. Your "old, experienced practitioner" will jog along through the ordinary run of cases of disease without the slightest mental uneasiness for his own part, and with perfect satisfaction to his patrons, while his neighbor, just out of college, will lie awake o' nights cudgeling his brains to get at the bottom of cases of the same sort; but let an unusual case arise, and the old doctor will be utterly nonplussed, simply from never having seen its like before, while the young man will bring his theoretical knowledge to bear upon the case, and with such telling effect that the knotty question will be how to enlighten the old gentleman without offending him.

Let not the young graduate think, then, that he has done with "book learning," and that henceforth he must devote himself to a laborious accumulation of precedents in his own experience. Let him rather keep on with his systematic study. We take it for granted that he will keep on with his reading, but in that reading let him not always be on the look out for points in practice, devices fit only for mere artisans; let him keep himself *au courant* not only of new facts, but of new views as well. Facts are good things to have, but it is not well to be prostrated under a pile of them; it is better to master them, to estimate them, to make them serviceable, by analysis and critical methods of thought. None are so apt to be led away by theory as those to whom theories are unfamiliar. Let our young practitioner take heart, then, and not be too much cast down by the thought of his own shortcomings.

THE HOSPITAL COURSE.

No man can be said to have prepared himself properly for a creditable career in medicine unless he adds some practical training, under competent supervision, to the learning he has acquired in the college course. Rarely will any other form of such training be found fully to take the place of a term of service on the house staff of a general hospital. We would, therefore, beyond all things else, urge the young graduate to leave no stone unturned to secure such a service. Even an opportunity to form a business connection with an established practitioner should not be allowed to stand in the way, for any man who is judged worthy of such an association at a time when he has barely emerged from the medical college is most assuredly the very one whom a hospital course will most develop, and to a certainty he is the very one who can afford to give up the glittering bauble of the present, and rely with well-grounded confidence on the incomparable advantage that such a training will bring him in the course of a few months. Too many men suffer all other considerations to be overshadowed by the reflex

tion that they have spent a good deal of time and money in acquiring the right to practice, and by the consequent conviction that they ought to begin earning a living as soon as possible. This is a grave error. In the long run, nothing is gained by beginning practice at an early age; one will achieve competence quite as soon by starting upon his actual work at the age of thirty as by setting out at the age of twenty-five. Time is not lost, therefore, but put out at interest, so to speak, by devoting it to the completion of one's education.

We do not mean to say by any means that the hospital course is absolutely essential to success in practice, for we are quite aware that our profession includes many men of deserved eminence who in their early years were compelled to forego the great advantage it confers; but we do say, and that without the slightest hesitation, that, of two men equally well prepared in other respects, he who has seen hospital service will tread a path comparatively smooth, while the other will have to wage a wearying warfare with the deficiencies that it is the precise result of such service to do away with.

What is the charm by virtue of which the hospital course does all this for a man? The fact that it gives him the best "graded course" possible, under the guidance of the best practitioners with whom he could by any means be thrown. We will state, in general terms, what it is. Having passed his hospital examination, the young man enters upon the duties of a Junior Assistant, or Junior "Walker." If his service is on the medical side of the house, but little is generally required of him in this grade: he makes the daily rounds with the House Physician, and again with the Attending Physician, drinking in *savoir faire* from both; when not thus engaged, he superintends the details of medication, especially of external applications, applies cups, leeches, and the like, passes the catheter, and does such other minor manipulations as may be thought a little too much for the nurse and rather beneath the dignity of the Senior; he also copies the latter's histories of cases into the record books. For the time being, he is a "general utility man"; but the familiarity with details he thus picks up is wonderful, and he really comes to be very "knowing." Become a Senior, his leading duty is to elicit and note down the patients' histories, and on occasions, he figures as "House" *pro tem*. When he actually becomes "House," he bears the immediate responsibility in the management of the cases; aided only by the Attending Physician's daily visit, he has the entire direction of the treatment. He thus acquires a confidence that never deserts him. On the surgical side the gradation is much the same, *mutatis mutandis*.

It will be seen that by degrees the young man advances from a position of no responsibility to speak of to one demanding and begetting the utmost self-reliance. In most, if not all, of our hospitals in New York the candidate for a position on the house staff of a hospital must first have passed his examination for the doctorate; in some cities, as we understand, this is not the case. It seems to us that the former system is by all odds the better one; it insures that all the medical officers of the hospital shall be "qualified" practitioners, and it allows the

young men to devote all their energy to the actual work before them, unhampered by the perfunctory systematic study of books that an impending examination really obliges them to undertake.

Something is to be said in regard to the choice between various hospitals. In the first place, we would advise a general rather than a special hospital. It need not be a large one, for too large a service requires so much sheer work in its performance that thoroughness of observation is apt to be neglected. The field afforded by a special hospital is of great value, no doubt, but, if possible, a course should first be taken in an institution where the practice includes the whole range of medicine and surgery. Least of all would we advise the young graduate to take a position in a lunatic asylum, but, for that matter, there is not much likelihood of his being able to get one. Psychiatric is so very special in its scope that it does little toward preparing a man for general practice; and, on the other hand, good service can scarcely be rendered in a lunatic asylum by those who have not had considerable training in a wider field.

We can not close without a word to those who are tempted to hastily conclude that a hospital career is beyond their reach. They can not all attain to it, to be sure, for hospitals are few; but any man who is fit for such an appointment can usually secure it in the end. Some of our best men have failed at the first trial, and afterward been rewarded with success. Above all, let our readers free themselves from the fear of favoritism. With very few exceptions, our hospitals are open to the best men, no matter whence they come or where they got their degree. At any rate, it is no disgrace to fail in the attempt, and they often succeed who enter the contest with but faint hope. In another part of this issue of the journal we give the leading details in regard to a number of the hospitals of New York, embracing information that we can vouch for as authentic. The statements there given have been prepared with great care, and we trust that some will thus be encouraged to try for a hospital course who otherwise might have felt themselves incapable of succeeding.

ALMA MATER

Of all impersonal attachments, there are few indeed that surpass in depth or in permanence the sentiment of reverent regard cherished by the doctor in medicine for the institution to which he owes his degree. As an undergraduate, he may have idled away an unconscionable proportion of the time nominally spent under the tutelage of alma mater, he may have scoffed at what it pleased him to call "dry" in the pabulum she set before him, over and over again he may have reviled her learned professors a set of bores, daily he may have reviled the benches she provided for him and his associates, and he may have chafed beyond all reason under the prolonged drudgery of the curriculum; but, when at last, after a long and arduous period of patient, he finds himself a member of the faculty, he prompts an unwilling mother to gaze in ecstasy upon her newborn babe.

The tie so subtly engendered never breaks. When the

is not to be dethroned. Let one of her children venture to slight her by taking an *ad eundem* degree; she need be at no pains to resent it, for the prudential reasons that he constantly finds himself pleading in an apologetic way are but so many witnesses to the truth of the old saw, *qui s'excuse s'accuse*. And indeed he feels that he has need to accuse himself. This very feeling avenges her and draws the bond tighter that binds him to her. Let him attain, in his own estimation, to some claim to distinction at her hands which she most ruthlessly declines to grant; he may feel galled, he may speak brave words of rebellion, but he can not break with her at heart. He may even forsake medicine, put on the livery of another mistress, and prate proudly of having thrown physic to the dogs; but he can not deny to himself, however jauntily he may disport himself among men, that her grasp is upon him still, or that it is one of love, not of coercion.

All this marks a bright spot in our tarnished nature; it lifts us over many a bog in which we should otherwise flounder hopelessly. The reign of *alma mater* is beneficent; she grants far more than she exacts, or than we can possibly render. How, then, shall we best do what little in us lies to give back some small portion of the debt we owe her? By so working in the service of that art she has bidden us follow that her labor with our successors may be the lighter; by so acquitting ourselves before our fellow-men that they may never taunt her with our misdeeds; by being always so true to her and to ourselves that she may never hesitate to say of us *hæc mea ornamenta sunt*.

ALUMNI ASSOCIATIONS.

ONE of the most practical turns that a man's love for *alma mater* can take is that of interesting himself in the association of her alumni. In the case of several of our leading colleges these associations have shown themselves not only promotive of the continuance of social relations between their members, but also highly conducive to the prosperity of the college and to the advancement of professional interests in general. Perhaps the most conspicuous example of this usefulness is to be found in the case of the Alumni Association of the College of Physicians and Surgeons of New York. Its organization is very carefully and prudently managed, and it has succeeded in acquiring a certain status with the faculty, essentially advisory, indeed, but none the less influential. It has set about accumulating a fund for the endowment of a chair of pathological anatomy; it has established a physiological laboratory, which, with some assistance from the faculty, it has maintained in a good working state for several years past; for many years now it has offered an annual prize of about five hundred dollars for the best essay on any medical subject; and, above all, it has provided an annual course of lectures—the Cartwright lectures, open to the whole profession. Two such courses have already been given—the first by Professor Bartholow, of Philadelphia, and the second by Professor Dalton, of the college faculty, and the third course, by Dr. Belfield, of Chicago, is now in progress.

The alumni of the Jefferson Medical College, of Philadelphia, seem to have devoted their energies more particularly to sustaining a journal, the "College and Clinical Record," a monthly publication that well represents the men who have interested themselves in its production, and no doubt tends powerfully to keep up an *esprit du corps* among them.

Of course, to accomplish such work as has been done in New York and Philadelphia, the alumni must be numerous. Consequently the younger colleges, and those seated in smaller communities, can scarcely be expected to achieve anything very striking through the agency of their alumni associations; but, even in the least pretentious of all the colleges, something can be done, or at least the foundation can be laid for good work in the future. It is, therefore, by all means desirable that such organizations should be formed in the case of every college, and that the alumni (or *alumnæ*, as the case may be) should support them zealously.

SPECIAL PRACTICE.

ONE of the most fatal errors that recent graduates are prone to fall into is that of attempting the practice of a specialty at the outset of their career. The idea is apt to find its way into their minds that the immediate adoption of a specialty is more likely to lead speedily to prosperity than the miscellaneous work involved in general practice. No notion could be more pernicious. Medicine can not be learned in parts, one to the exclusion of another; all its branches so interlace that their practical as well as their theoretical study must go hand in hand. We do not decri legitimate specialism, for we believe that medicine is more advanced by its special practitioners than by those who divide their forces in the vain attempt to achieve distinction throughout the whole range of the art; but we do deprecate, and that most earnestly, the resort to a specialty without good and sufficient reason in each individual instance. We speak, of course, of the practical branches; there is no objection to a man's devoting all his energies to one of the subsidiary branches—pathology, physiology, or anatomy—so far as we know.

In comparison with the great body of physicians, there are very few real specialists, excluding those who give themselves the name for prudential reasons; and of that small number the great majority are men who, far from setting out deliberately at the very start as specialists, fell into special practice rather from the gradual development of a particular aptitude, from the accident of opportunity, or even from such a fortuitous circumstance as the fact that they found themselves gradually bound by non-medical engagements of a sort to preclude general practice.

No man can become a good specialist until he has spent a number of years in the practice of general medicine. He may acquire special manipulative skill, but that is not medicine; he may master a special literature, but that does not make him learned. We have known men with both these accomplishments make a pitiable show in an assemblage of physicians. Not only should a considerable amount of general practice precede the adoption of a specialty, but, even after entering upon a

special career, general medicine should not be given up wholly. Pure specialists advance the special branches to which they are attached, but it is those specialists who do not lose sight of the broad domain of medical practice that advance the art of medicine as a whole. By all means, then, let the adoption of a specialty come, if it must come at all, as the result of development, and not as a gratification of fancy.

THE MATERIAL OUTFIT.

With all the natural acumen a man may possess, and with all the education he may have fortified himself with, there are certain material appliances without which it is vain to attempt the practice of medicine at the present day. No one man needs them all; some need more of them, some fewer. In general terms, these appliances may be divided into instruments, materials for dressings, and more or less of a stock of medicines.

Of all of them, he whose lot is cast in the country will require more at the outset than his city *confrère*, for the latter, being near the sources of supply, may forego the acquisition of the greater number until he actually has occasion to employ them, whereas the country practitioner must be *nunquam non paratus*. There can be no question, however, but that both are apt to imagine at the start that it is well to provide themselves with an imposing array of instruments, and the like, most of which will never be of any more use to them than the show-bottles in an apothecary's window.

Discretion comes into play very decidedly in the selection of such appliances as the physician needs to have in his possession. There are certain articles of every-day use that can not be omitted, of course—the thermometer, the hypodermic syringe, the pocket-case of minor instruments, a spirit-lamp, a specific-gravity bulb, a few test-tubes, and the more ordinary reagents for testing urine. These must be had; the question is, how to select them. The first piece of advice we have to give is, do not buy articles that are cheap. Nothing is sold much below the ordinary price unless there is some factor in the case that will afterward account for the low price, to the disgust of the purchaser. It would be well for the graduate to buy the usual necessary outfit before leaving the city in which he has pursued his college course, and it will be of advantage if he can get some older practitioner's advice in its selection. If he happens to have taken his degree at a country college, it would be better to write to some acquaintance in the city, rather than correspond directly with the dealer, for the latter, with the best intentions possible, is quite likely to misunderstand his customer's wishes. Much disappointment would often be saved by paying a physician for the trouble of making the selection.

As a general thing, it is not well to invest in novelties. Often an instrument that seems extremely well adapted for the purpose it is intended to serve will turn out to be of little or no practical use. Appliances made of soft rubber had better not be obtained until they are really wanted for use, as that material is apt to deteriorate rapidly.

In regard to medicines, it is mostly the country practitioner that needs to keep them on hand, but even him we should advise not to invest heavily in them, unless the field of his practice is quite remote from an apothecary's. For the few articles that are indispensable, the elegant preparations now furnished by the manufacturing pharmacists will almost suffice, and the physician will not find himself loaded down with bulky and perishable liquids. Among these preparations, the tablets, tablet triturates, etc., as devised by Dr. Fuller, seem to us admirable. Blank sugar-of-milk tablets are to be had, and can be

impregnated with almost any liquid drug of which the dose is small. So convenient are these preparations, indeed, that many city practitioners are getting more and more into the habit of keeping them. In the matter of drugs, too, it is well to avoid novelties, except under unusual circumstances. We would repeat, also, what we took occasion to remark in regard to instruments, that it is poor economy to buy cheap articles. They are always dear at any price.

THE MEDICAL CORPS OF THE NAVY

CONCERNING the medical service in the navy, we have little to add to what our Washington correspondent writes in the letter published in this number of the journal. Assistant Surgeons enter the service with the "relative" rank of Ensign or Master, corresponding to the rank reached by graduates (of the line) from the Naval Academy who had entered that institution six years earlier. At present they all enter as Ensigns. The six years' constructive service is allowed by law, to compensate for the time spent in preliminary education by the medical officer, and is supposed to correspond to the time spent by the line officer as cadet and midshipman.

On entering the service, the Assistant Surgeon is paid at the rate of \$1,700 a year when at sea, \$1,400 when on shore duty, and \$1,000 when on leave or waiting orders. After three years' service, two of which must be at sea (or, as now ruled, in a receiving-ship), the Assistant Surgeon is entitled to examination for promotion, and, if successful, becomes a Passed Assistant Surgeon, with the relative rank of Master or Lieutenant, and is paid \$2,000, \$1,800, or \$1,500, according as he is at sea, on shore duty, or on leave. After five years, his pay is increased to \$2,200, \$2,000, and \$1,700. Since 1846 it had been the law that the second examination, like the first, should be competitive, the officer taking new rank accordingly. By the law of 1877, however, this rule was changed, and the place gained on the register at the first examination remains unchanged. Subsequent promotions are by seniority only, and the examinations are, by usage, less rigid than the first two, the officer's record becoming an important element in the decision.

Surgeons have the relative rank of Lieutenant or Master, and are paid: the first five years, \$2,800, \$2,400, \$2,000; the second five years, \$3,200, \$2,800, \$2,400; the third five years, \$3,500, \$3,200, \$2,600; the fourth five years, \$3,700, \$3,600, \$2,800; after twenty years, \$4,200, \$4,000, \$3,000. Medical Inspectors have the relative rank of Commander, and Medical Directors that of Captain, which is the highest grade attainable by a staff officer, excepting the Chief of the Bureau, who, while so acting, holds the relative rank of Commodore. Directors and Inspectors, *while at sea*, are paid \$4,400 a year; under other circumstances the rank gives no advantage in the way of pay. Directors are seldom sent to sea.

A candidate for admission to the medical corps of the navy will have no difficulty in getting a permit to appear on presenting a certificate of good moral character and a letter from his preceptor. Political influence tends rather to hurt than to help him. He writes a "preliminary letter," answering certain questions as to his birth, education, etc., and undergoes a very rigid physical examination. The next day he writes a thesis. The following day he writes answers to from ten to fifteen written questions usually covering points in anatomy, physiology, surgery, practice, materia medica, chemistry, and therapeutics. Then follow about two days of oral examination, and one devoted to operations on the cadaver, the recognition of cases by their appearance, the use of the microscope, and other instruments of special application to diagnosis in hospital wards, and the writing and compounding of prescriptions.

A good deal of importance is attached to literary and scientific attainments, and especially to a knowledge of spelling, grammar, and precision in writing. Other things being equal, a college bred man is therefore likely to take higher rank than another, but the "humanities" are not essential.

THE ARMY MEDICAL CORPS.

It may not be amiss to give a few facts supplementary to the general information contained in Dr. Asch's article. At the time of the Surgeon-General's last annual report, dated October 1, 1882, there were six vacancies in the grade of assistant surgeon. To give some idea of the prospect the ordinary medical graduate has of obtaining admission to the medical corps of the army, we will state, on the authority of the same report, that an army medical examining board convened in New York on the 7th of November, 1877, and continued in session until June 30, 1882, and that during its session two hundred and fifty-eight candidates were invited to appear for examination, of whom forty-two failed to appear, one hundred and twenty-six withdrew after a partial examination, fifty-one were rejected, and thirty-nine were found qualified.

We mention these facts not for the purpose of discouraging young men who may have an idea of attempting to obtain admission to the medical service of the army, but simply that they may enter upon the contest with their eyes open, and without any deceptive notion as to the difficulties to be encountered.

THE MARINE-HOSPITAL SERVICE.

The United States Marine-Hospital Service, an adjunct of the Treasury Department, has for several years past most systematically and satisfactorily performed the work of caring for those of the sick and injured sailors of the merchant marine that have been admitted to the various marine hospitals established throughout the country. Most of these hospitals have been in operation for several years; but in former times, although some of them were well managed, they were not free from influences that tended to impair their usefulness, chiefly that stagnation that so readily besets men when their work is not supervised by others, or reasonably open to general inspection. All this has been changed by the admirable organization of which we are speaking, and the staff of the Marine-Hospital Service has become one in which membership is in the highest degree creditable and advantageous. The clinical opportunities afforded by the service are large, as shown by the fact that 36,184 patients were treated during the year ending June 30, 1882. Quite recently the staff has been charged by Congress with important sanitary functions appertaining to epidemics, so that the service now gives opportunities for acquiring practical knowledge relating to the management of pestilential diseases. Elsewhere in this number of the journal we give some facts in regard to the steps necessary to be taken to obtain an appointment to the Marine-Hospital Service.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

A STATED meeting was held December 26, 1882, Dr. T. M. MARKOE, President, in the chair.

EXCISION OF THE ARTICULAR EXTREMITIES OF THE PHALANXES.—Dr. ALFRED C. POST presented a patient upon whom he had operated for the relief of an angular deformity of about

fifty degrees of the index-finger of the left hand. It was one of a class of cases in which he had operated a considerable number of times within the past few years by excising the end of the phalanx. About fourteen years ago this patient had his finger dislocated while playing base-ball. The dislocation was not reduced, and the terminal phalanx remained flexed at about the angle mentioned. For some time before he came under Dr. Post's observation there had been suppurative disease, and, on examination, there were found two sinuses leading down to rough bone. The operation, therefore, was performed not merely for the correction of the deformity, but for the removal of the carious portion of bone, and in this instance, instead of excising the distal end of the proximal bone, he excised the diseased portion of the ungual phalanx. The operation had been performed a little more than three weeks, during which time the finger had been supported by a splint. Three days ago the splint was removed, and the parts were supported by adhesive plaster. The wound healed readily, and the deformity had been corrected. Dr. Post said that the operation, in his experience, had not been attended by so much irritation as had amputation of the phalanx. He had applied the same operation to the phalanges of the toes. He had not met with any instance in which there had been any considerable amount of irritation following the operation. He believed that the wounds healed quite as readily as after amputation. He had not succeeded, of course, in securing a perfect joint, although there had been in nearly all the cases some motion. The after-treatment consisted in keeping the parts supported until they became sufficiently firm to sustain themselves.

THE PRESIDENT then read the following paper on TRIPIER'S MEDIO-TARSAL AMPUTATION:

During my residence at the New York Hospital, in the years 1839-'40-'41, one of our best surgical nurses, a man named George Compton, had lost both of his feet by amputation through the tarsus by Chopart's method. He wore on each foot a shoe, not very ingeniously contrived, nor very neatly constructed, but one which, nevertheless, by much forbearance and not a little suffering, he was able to wear occasionally, and to stomp about his ward with considerable agility, which certainly was the reverse of graceful. I remember that he used to pad his shoes very carefully with layers of old blanket, cut to fit the stump, and then to lace them very tightly round the ankle and part way up the leg. Thus provided, he was able to get about with some comfort for a certain time; but soon the pressure upon the cicatrices gave rise to pain and soreness, frequently terminating in most intractable ulceration, and it must be acknowledged that, brave as he appeared in his shore toggery on Sunday morning, as he walked down the front avenue leading to Broadway, he would commonly come back in the evening wearied and limping, and glad enough to get rid of his uncomfortable shoes, and only too happy to be allowed to stomp about on his knees. Of course, he was not at all times equally disabled. Several of the surgeons of the hospital tried to improve his stumps by various operations and modes of treatment, but without any permanent benefit, and to the last his active and useful life was rendered miserable by the constant irritation of ulcerated and tender stumps, and his intelligence and courage and endurance only showed what a prize he might have won in life's race if he had not been so heavily handicapped. I did not then study the position and relation of the bones, as I should be only too happy to do now; but this I remember, that his chief trouble arose from the frequent and intractable ulcerations of the face of the stump, showing that the cicatrix bore the chief weight of the body when he walked, and was, therefore, constantly suffering from the effect of pressure directed immediately upon it.

This unfavorable behavior of the stump left by Chopart's

amputation has been noticed by all the surgeons who have had much to do with this operation, and much thought and ingenuity have been expended in endeavoring to explain and to obviate it. In regard to the cause, all seem to be agreed that it depends upon a change in the position of the stump, whereby the heel being forcibly drawn up, the front part, or the cicatricial face, is thrown downward, so that, instead of resting on the natural plantar cushion of the inferior surface of the stump, this anterior surface receives the whole weight of the body. It is somewhat remarkable that so wide a diversity of opinion should exist among really good observers as to the reason of this change. It would seem to be a simple and adequate explanation of the deformity to say that it is due to the unopposed contraction of the gastrocnemial muscles; but I find that at a recent meeting of the Société de Chirurgie, in Paris, a M. Larzer read a paper on the causes of the tilting of the heel after partial amputations of the foot, and arrives at the conclusion that it is due solely to the atrophy of the anterior muscles of the leg, and not at all to the action of the calf muscles, which, he asserts, take no active part in the change of the position of the heel. Acting upon this theory, he applies electricity to the weakened muscles, and insists that any other treatment is entirely unphilosophical, and, therefore, useless. The report of the committee, to whom this paper of M. Larzer was referred did not accept the exclusive views of the writer, and, while they acknowledged the possible occurrence of the atrophy in question, they felt that they could not ignore the powerful influence of the muscles of the calf. In the course of the discussion which followed, M. Verneuil contended that both the anterior and the posterior muscles of the leg undergo atrophy after these amputations, and that, therefore, neither of them have anything to do with the displacements in question.

By all the older, and by far the larger number of the best modern authorities, the calf muscles are fully recognized as the active agents in producing, or, at the least, in perpetuating the deformity. The main practical question, it seems to me, is, What other vital or mechanical conditions favor, though they may not originate, the undesirable position which the foot is so apt to assume? That there are other causes which at least contribute to this undesirable result would seem to be proved by the fact that division of the tendon has been recommended by many of the best operators, and yet it is universally acknowledged that this procedure does not by any means always prevent the deformity, and still less cure it when it has occurred. Let us look now at one of these accessory causes, to my mind a very important one, and see what practical relation it may have to the main cause, and to the prevention of the trouble.

While the patient is in a standing position, the tendency of strong contraction of the gastrocnemial muscles is to draw up the heel, and thereby extend the foot upon the leg. This movement is resisted by the long lever of the foot pressing upon the ground, and thereby preventing the extension from taking place. The only effect, then, of moderate action of the several muscles is, to keep the foot firmly planted on the ground, and at the same time to prevent the body from falling forward. If now the action of the calf muscles be much increased, the ball of the foot remaining in contact with the ground, the effect will be to raise the posterior part of the foot, and with it the whole body, which rises as the act of extension of the foot on the leg is accomplished. The action results from the power acting on the short arm of the lever moving the resistance on the fulcrum which is at the end of the long arm of the lever.

Now, I am supposed that, as happens in Chopart's amputation, the long arm of the lever is removed by the separation between the scaphoid and astragalus; and then we should have the power, A (Fig. 1), unopposed by the fulcrum, C, and, therefore, unable

to counteract the resistance, B, which would force the astragalus downward until it came in contact with the ground. This becomes plain on glancing at Fig. 2.

FIG. 1.

If now the unopposed power continues to act, its only further effect, after the astragalus has reached the ground, must be to raise the heel higher and thereby roll the astragalus in its mortise between the malleoli so that its anterior face looks more and more downward, until finally it comes to press directly on the ground. It must not be forgotten, however, in thus estimating the action of the several muscles, that, if their influence should be entirely eliminated, as by tenotomy, for example, there would still remain, in the obliquity of the under surface of the bones remaining after a Chopart's amputation, a mechanical reason why the heel should rise and the astragalus descend, as soon as the weight of the body is brought to bear, as in the act of standing. These two causes, then, conspire to produce the result we are considering, viz.: 1, the unopposed contraction of the gastrocnemial muscles; and, 2, the oblique surface, in reference to the level of the ground, presented by the inferior surface of the bones which constitute the stump. When now we add to these statements the facts that the ligamentous tissues around the ankle-joint soon become so contracted and so rigid in their changed position that even when the tendons are cut they will obstinately maintain the displacement, we have related the chief if not the only causes which produce or perpetuate the deformity now under consideration. A review of these different causes shows also why it is that the

FIG. 2.

deformity is not in every case cured, and that the tendon of the Achilles, and particularly why that operation, performed after the lark-heel has become established, does, in many cases, so little to improve the usefulness of the medio-tarsal stump.

The study of the various mechanical actions of the foot, and the fact that the long arm of the lever is removed by the separation between the scaphoid and astragalus, and then we should have the power, A (Fig. 1), unopposed by the fulcrum, C, and, therefore, unable

Lyons, and which has since gone by his name. It may be considered as a modification of Chopart's amputation in so far that the astragalus and calcaneum are left, but it differs from it in this: that a segment is sawed off from the lower part of the os calcis in such a way as to leave the lower or plantar surface of the bone showing a line parallel with the surface of the ground on which it bears in standing or walking. This section is made at the level of the sustentaculum tali in such a direction as to bring the line of the saw-cut at right angles to that of the tibia, leaving, therefore, a bone surface which, when the weight of the body is brought to bear on the stump, will have no tendency to change its relation parallel to the ground on which it rests. This is the principle of the operation, and its originator claims for it great success. The cases in which the operation has been tested thus far are very few in number, and time enough has not yet elapsed to enable us to reach a final verdict as to its merits. In the "British Medical Journal" of February 26, 1881, Dr. P. I. Hayes, of Kingston, Surgeon of the Mater Misericordiae Hospital, reports a case in which he operated in this method, the man making a good recovery and walking without a crutch in a month. He has since reported the operation with a like satisfactory result. Mr. Wagstaffe, in the "London Medical Record," discusses the merits of this operation, and approves of it as likely to prevent the tilting heel. He contrasts the operation with the subastragalar, and gives preference to the method of Tripier. He does not say that he has ever done the operation.

Tripier's amputation is performed by an incision which commences on the outer border of the tendo Achillis, on a level with the outer malleolus, passes downward and forward, skirting the malleolus about one inch below it, passes then along the outer border of the foot, rather more toward the dorsal than the plantar surface, till it reaches the base of the metatarsal bone of the little toe. The line of incision here turns upward and inward, passing across the dorsum of the foot till it reaches the base of the metatarsal bone of the great toe, and there, turning downward and forward into the sole, is continued across the sole, making a convex flap at least an inch longer than the dorsal. When it reaches the outer border of the sole it turns backward and upward, and joins the original incision at an oblique angle on the outer side of the foot. The flaps thus marked out are raised so far as may be necessary to disarticulate between the astragalus and the scaphoid, and between the os calcis and the cuboid, leaving behind the astragalus and os calcis, so that they can be exposed as high as the sustentaculum tali; this part of the operation resembling the dissection round the heel in Syme's amputation at the ankle joint. When the lower part of the calcaneum is thus fully exposed, it is to be sawed through just below the level of the sustentaculum, so as to make the line of saw-cut as near as may be at right angles to the line of the tibia when the patient is standing, and, therefore, parallel to the line of the ground on which it is to be placed. The section of the bone is recommended to be made from within outward, thereby more surely avoiding any injury to the posterior tibial artery, which, from its importance, bearing on the life of the plantar flap, is to be most carefully guarded. Having made sure that the section of the bone has been made in the desired line, the sharp edges and corners of the bone are to be removed with cutting forceps, and the flaps brought into place and united by many sutures. Proper drainage tubes being placed, and a supporting dressing applied which shall hold the lower flap well in its place, the operation is completed.

I performed the operation in the following case: John Ohmer, a German, aged thirty-three, a waiter by occupation, was admitted to the New York Hospital April 18, 1882. His health had been good until about four months previous, when, without

any known cause, his left ankle became swollen and painful. The trouble rather slowly increased, he continuing to walk about for nearly a month, when his ankle became so distressing to him that he took to his room, and finally to his bed. The further course of the disease was one of steady increase, with increasing and finally severe and constant pain. On admission, the tarsal region was recognized as the seat of the disease, the swelling, however, extending up to the ankle joint. The swollen parts were very hard, and tender to the touch, and the whole region was hot and painful, but without much redness of surface. After a time obscure, deep fluctuation could be discovered, and some crepitation could occasionally be elicited by moving the metatarsal bones on the tarsus. Deep incisions were made, letting out a great deal of pus. The parts were poulticed, and everything was done that we could think of to improve his general nutritive condition, but without result. The abscess did not heal. Fistula remained. Pain was not mitigated. In short, the carious disease was making constant progress. On the 20th of May the actual cautery was applied at several points on the dorsum of the foot, but, beyond relieved pain, no benefit could be traced. The question of amputation soon decided itself, and, inasmuch as we felt confident that disease was confined to the anterior row of the tarsal bones, it was regarded as a suitable case in which to make a trial of Tripier's method. The amputation was done on the 7th of June, precisely in accordance with the description given above. Particular care was taken to make the plantar flap as liberal as possible. All the fistulae leading down to carious bone were included in the part removed, except one which remained on the inner side of the stump. When the disarticulation was accomplished, the remaining bones were carefully examined, and were considered to be free from disease; and the section of the os calcis revealed bone tissue, softened, indeed, from the atrophy of disuse, but, as far as we could judge, free from present disease. The flap fitted exceedingly well, and covered the bone without the slightest tension. Everything proceeded to our entire satisfaction during the first few days after the amputation. The wound healed almost entirely by the first intention, and he improved very greatly in his general condition as soon as he was released from the irritation caused by the carious bone. The local conditions, however, did not long continue favorable. Part of the wound broke open, and gave issue to pus, which it was soon evident came from a deeper source than the surface granulations. The stump became swollen and painful, and it became clear that carious disease had attacked the astragalus, and probably the os calcis. His general condition began now pretty rapidly to depreciate, and, though the operation wound was for the most part soundly healed, we were convinced that there was hopeless local disorganization of the bones, and that reamputation was the only thing that could save his life. The limb was accordingly amputated through the lower part of the leg on the 8th of August, just two months after the previous operation had been performed. He made a rather slow, but ultimately a perfect recovery.

As far as the cure of the disease was concerned, Tripier's amputation, in this case, was not a success, the mischief spreading to the bones left in the stump, and requiring another operation for its eradication. This feature has, however, no particular bearing on the amputation itself, which is the subject we are now considering; and it may be said, generally, that in all these partial operations on the foot, and also on the hand, some uncertainty must exist, first, as to whether any disease of the bones has been left behind, or, secondly, whether the bones, now healthy, may not take on diseased action in the future. As a rule, I think this point ought, with care, to be determined with substantial accuracy, and, in point of fact, recurrence of disease

has been found to be rare. I am aware that Mr. Syme says: "In this operation the astragalus and os calcis are left, and though they appear sound at the time of operation, yet the disease frequently recurs, as you may learn from the fact that I once performed three secondary operations within the period of twelve months upon stumps in which Chopart's operation had been practiced." On the other hand, Mr. Hancock replies: "This objection, thus forcibly urged by Mr. Syme, is, I am aware, maintained by other surgeons; but it is not supported by the statistics of the operation, since of one hundred and four cases, exclusive of those mentioned by Mr. Syme, I find only two followed by secondary amputation, and this for retraction and painful cicatrix, and not for recurring disease."

The new operation seems to me to offer a satisfactory substitute for a very unsatisfactory one, such as in many cases Chopart's amputation is conceded to be. It is an operation not yet proved, scarcely fairly tried, and it would, therefore, be unwise to pronounce too positively on its merits. That it is feasible, that it makes a good stump, is settled by the few cases in which it has been done. That it certainly and perfectly obviates all the disadvantages of the amputation which it is proposed to displace we can not be sure. I can only say that, as far as theoretical considerations go, and as far as a very few cases can be trusted, it seems to promise well, and I challenge for it the careful consideration of those who may have occasion to perform a medio-tarsal amputation.

Dr. Post referred to another operation, which furnished better results, so far as usefulness of the limb was concerned, than did Chopart's—namely, that performed by Dr. Quimby, also claimed by Dr. Turnipseed, of South Carolina. It consisted in a modification of Pirogoff's operation, but differed from it in the fact that the lower extremities of the tibia and fibula were left entire, the cut surface of the os calcis being brought in contact with the cartilage covering the lower extremity of the tibia. Dr. Quimby had performed the operation three times, and Dr. Post had performed it twice, and in all the cases there had been a good stump, and no inconvenience had resulted from want of homogeneity of the parts brought together. The wounds had healed kindly and the stumps had been firm, and the operation had been attended by only a moderate amount of shortening.

Dr. L. A. Stimson said the idea of the operation referred to by Dr. Post was not novel. It had been considered by Pirogoff himself, and, he believed, also by the English surgeon Ure, who devised the operation at about the same time as Pirogoff. The suggestion has been frequently referred to, and generally condemned. The lower end of the tibia is saved off in Pirogoff's amputation, not because surgeons do not know that bone and cartilage can unite, but mainly because of the difficulty of otherwise keeping the end of the calcaneum from being drawn up by the tense tendo Achillis—the same reason that has led to modifications in the direction of the line of section of the calcaneum, or of both bones. Dr. Stimson also asked if it had been found difficult to perform Tripier's operation.

The PRESIDENT remarked that there was no greater difficulty in the performance of the operation than obtained in Syme's or Chopart's, except with reference to following the line of the cicatrix.

Dr. CHARLES McBURNEY had performed Chopart's operation in one case in which there was anchylolysis of the ankle-joint not produced by disease, but by long confinement in one position. The patient made an excellent recovery, and had a useful stump. That fact suggested to him the question as to whether sufficiently strict attention had been paid to retaining the stump in proper position for a sufficient length of time after Chopart's operation had been performed. The idea was to retain it in position for a sufficient length of time to allow a certain loss of

muscular power to take place, so that there would not be a marked antagonism between the anterior and posterior groups. He could easily imagine that the stump after Chopart's operation might bend downward within two weeks if allowed to follow its own course. He asked Dr. Markoe if he was able to give any information upon that point.

The PRESIDENT replied that, so far as he recollected, none of the authorities had directed attention to the question raised by Dr. McBurney. It seemed to him, however, to be a reasonable suggestion; and it also seemed to him that the mechanical factor—even with atrophy of both sets of muscles, the os calcis touching the ground first—was the great factor of the operation. Contraction of the muscles was probably another important factor.

Dr. H. B. SANDS believed that the neglect to prevent this extreme extension of the foot after Chopart's operation had been recognized by European continental surgeons as, perhaps, the main cause of the subsequent difficulty in locomotion. He believed it had been claimed that, if extension of the foot was duly prevented during the course of the treatment immediately following the amputation, it would not subsequently take place to such a degree as to bring the cicatrix in contact with the ground, provided the former was not placed too near the plantar surface. He believed that the verdict given by American surgeons against Chopart's amputation had not been sustained by statistics. The statistics given by Max Schede proved that the limb after Chopart's operation was not more frequently useless than after other partial amputations of the foot. There was only ten per cent. of useless limbs after Chopart's operation. He thought that Chopart's operation was entirely legitimate, provided the astragalus and os calcis were both sound. There was an objection to both Chopart's and Tripier's operation—namely, that when chronic disease invaded the tarsal bones it was apt to implicate, sooner or later, all of them, and thus there might occur, as in the case related, extension of the disease after performance of the operation, so as to render necessary amputation at a higher point. Some years ago Mr. Hancock proposed in cases of partial amputation to regard the foot as a whole, and to operate without reference to the articulations, forming the flaps and sawing the bones as might be expedient. Dr. Sands thought that the suggestion made many years ago was particularly useful in these days of antiseptic surgery, when operation wounds, whether of bones or joints, were so likely to pursue a favorable course.

Dr. ROBERT F. WAIN supplemented Dr. Sands's remark by the statement that Hancock also suggested the removal of a small section of bone so as to counteract the contraction of the posterior group of muscles.

Dr. CHARLES K. BRIDGON said that within the last two weeks a patient came under his observation who had had Chopart's operation performed two years ago. Since that time he had been incapacitated in going about on account of painful ulceration in the line of the cicatrix; the whole of the anterior surface of the stump was covered with cicatricial tissue, and a spot of about the size of a quarter of a dollar was in a state of ulceration. He thought the ulcerated condition was not attributable entirely to the operation, inasmuch as the operation had probably been performed in apparently healthy tissues. The original injury was a railroad accident, and he thought it probable that, as is commonly the case in railroad accidents, the vitality of the tissues was, to a greater or less extent, destroyed to a point higher than that at which the amputation was made, so that the closing of the flaps took place, making them scanty and tense, and ulceration occurred after repeated cicatrization. As a further operation he had recommended Syme's amputation.

(To be concluded.)

Miscellany.

HOUSE STAFF POSITIONS IN NEW YORK HOSPITALS.—For information in regard to the several hospitals in New York, Dr. Roosa, in an article contained in this number of the journal, refers his readers to the "Medical Register." That volume will be found to give many facts in point, but we think the recent graduate who contemplates trying for a hospital appointment will look upon the following supplementary data as furnishing him with points that he could not otherwise obtain readily:

New York Hospital.—This is the oldest hospital in New York, having been founded in 1770. Its history has always been creditable, and within its walls many of the most brilliant feats of American surgery have been accomplished. For many years it has been noted for the precision attained to by its house staff in matters of minor surgery, so much so that during the late civil war many an army surgeon was heard to exclaim, after witnessing an uncommonly clever application of a bandage: "That man must have come from the New York Hospital."

The house staff consists of a House Physician and a House Surgeon, and their senior and junior assistants—six in all. The term of service is eighteen months, six months in each grade. The appointments are made on the 1st of June and the 1st of December of each year, by the Board of Governors, on the recommendation of the Medical Board. Graduates of any regular medical college are eligible, and the two who pass the best examination (in writing and orally) are nominated. Candidates must make written application to the Secretary of the Medical Board, Dr. Woolsey Johnson, and the application must be indorsed by one of the Consulting or Attending Physicians or Surgeons. Except the Junior Assistant Physician, all the members of the house staff reside in the hospital. On the Surgical Division, from one to three Dressers are appointed, for a period of from three to six months, by the Attending Surgeon on duty at the time. They are usually selected from the unsuccessful candidates at the examination, do not reside in the house, and are not in the line of promotion. One of them acts as Junior Assistant in case of the absence of any member of the house staff. The ambulance service is in charge of the Junior Assistant Surgeon, assisted by the Dressers. Diplomas are awarded to the outgoing members of the staff. As a rule, patients with chronic diseases are not admitted, so that the service of the house is very active.

Bellevue Hospital.—In this large hospital there are eight divisions, four medical and four surgical, to each of which three members of the house staff are attached, making twenty-four in all, besides two ambulance surgeons (the latter not in the line of promotion). The term of service is eighteen months, six months in each of the three grades of Junior, Senior, and "House." Vacancies occur on the 1st of April and the 1st of October. The method of appointment is peculiar: of the eight vacancies that take place every six months, two are filled on the nomination of those members of the Attending Staff who are connected with the College of Physicians and Surgeons; two on that of the members attached to the Medical Department of the University of the City of New York; two on that of those belonging to the faculty of Bellevue Hospital Medical College; and the remaining two on that of those who have no college connection. We understand that the two last named get their nomination as the result of a competitive examination, and that those appointed on behalf of the College of Physicians and Surgeons are the "honor men" in the college examination for the degree of M. D. So far as is compatible with all these requirements, the places are open to all applicants, suitability being the only test. The service at Bellevue is very large, including a lying-in service at the Emergency Hospital, also a term in the lunacy pavilion, each of which is taken by the several members of the staff in turn. The advantages of this hospital for bedside instruction are made the most of by the Attending Physicians and Surgeons, much to the profit of the house staff. None but the House Physicians and House Surgeons reside in the house, except that that one of the surgical Juniors who may be in charge of the erysipelas service (which they take in turn, each for a term of six weeks) lives in the house while on that duty.

Roosevelt Hospital.—There are six gentlemen on the house staff—a House Physician, a House Surgeon, and a Senior and Junior Assistant under each. The term of service is eighteen months—six months in each grade. Vacancies occur on the 1st of June and the 1st of December, the examinations being held in May and November. Competitive examination is the test, appointment depending solely on the candidate's general fitness, although, other things being equal, graduates of one of the New York city schools are preferred. One of the special advantages of this hospital is, that there is a well-conducted gynecological service attached to the medical division. Members of the house staff reside in the hospital during their whole term of service. Applications should be made to the Chairman of the Committee on Examinations, Dr. Henry B. Sands, 35 West Thirty-third Street. Notice of the date of the examination is usually published.

Charity Hospital.—The house staff consists of twenty-four men—eight divisions, each comprising a "House," a Senior, and a Junior, who serve six months in each grade (eighteen months in all). Vacancies occur April 1st and October 1st. Competitive examination is the sole test. The range of the services is greater, and the patients are more numerous, than in any of the other hospitals. The departments are medical, surgical, venereal, dermatological, ophthalmological, otological, laryngological, and gynecological, and there is a ward for convalescent puerperal women. The members of the house staff reside in the house only during the last six months of their service, but the Senior and Junior Assistants are provided with luncheon.

St. Luke's Hospital.—The house staff comprises six men—a House Physician and a House Surgeon, each with his Senior and Junior Assistants. The term of service is eighteen months, including six months in each grade. Vacancies occur in June and December. Candidates have to submit to a competitive examination (orally and in writing), after having been passed upon by the Executive Committee of the Board of Trustees. Residence begins at the close of the first six months.

German Hospital.—The arrangement is peculiar: vacancies do not occur at stated times, but a contract is made with the appointees, by virtue of which they undertake to serve at least one year, and so long a time in addition as it pleases both parties, three months' notice by either party working an annulment of the contract. The staff consists of a First, a Second, and a Third House Physician, and a non-resident assistant, advancement in grade taking place whenever a vacancy occurs. No competitive examination is required, but suitability is the only test, stress being laid on good technical training and executive capability. Graduates of German schools are preferred, but at present there are three Americans on the staff. The particular advantages of a service in this hospital are thought to be the strictness of its discipline, the constant attention of the Medical Board, and the fact that a very large and valuable medical library is open to the use of the staff. The First House Physician is paid an annual salary of \$350; the Second, one of \$250; and the Third, one of \$200.

Mt. Sinai Hospital.—The house staff is made up of a House Physician, with his Senior and Junior Assistants, and a House Surgeon, with his Senior and Junior Assistants. The term of service is eighteen months—six months in each grade. Vacancies occur on the 1st of June and the 1st of December, the examinations being held in May and November. Appointment depends solely on merit. There is a special children's service attached to the medical division, and an ophthalmological and otological, together with a gynecological service, connected with the surgical division. Residence begins at the close of the first six months, and meals are provided for the Juniors.

Presbyterian Hospital.—Four men compose the house staff; each serves two years in all—six months successively in each of the positions of medical Junior, surgical Junior, House Physician, and House Surgeon. Vacancies occur on the first of June and the first of December. Application should be made to the Board of Management, who examine into the candidates' moral qualifications, and only their nominees can be examined by the Medical Board. The medical examination is the final test. The appointees must be graduates in medicine. The alternate medical and surgical service is considered to be of great advantage. The members of the house staff reside in the hospital during their whole term of service.

St. Francis's Hospital.—The house staff consists of five:—a House Physician, a House Surgeon, two First Assistants, and a Second Assistant. The term of service is eighteen months (six months in each grade). Vacancies occur the last of March and the last of September. Competitive examination practically decides the question of appointment, but men who speak German are preferred. Each member of the staff serves alternately on the medical and the surgical side. The latter includes a gynecological service. None of the house staff reside in the hospital, but all of them are furnished with luncheon.

Clumbers Street Hospital.—A House Surgeon and his Senior and Junior Assistants compose the house staff, and the term of service is one year (four months in each grade). Vacancies occur the first of February, the first of June, and the first of October, candidates submitting to a competitive examination, written and oral. The Junior acts as Ambulance Surgeon, and assists both the Senior and the House Surgeon. The Senior is occupied mainly with the out-patients. The House Surgeon, in addition to the duties that fall upon that officer in other hospitals, keeps the records, a work performed in most hospitals by the Senior. The out-patient department employs three or four supernumerary assistants (either graduates or third-year students), who serve from two to five hours a day, under the direction of the Senior. We understand that there is a probability that a change will soon be made, so that the department will be in charge of an out-patient surgeon, who will attend from nine or ten o'clock in the morning until noon, every day but Sunday, being responsible directly to the Attending Surgeon, who will inspect all patients twice a week, besides making daily visits to those in the wards. All the members of the regular house staff, including an additional Ambulance Surgeon, but not including those who serve as assistants in the out-patient department, reside in the house. The supernumerary Ambulance Surgeon is appointed for a term of two, three, or four months, without undergoing an examination.

St. Vincent's Hospital.—The house staff consists, so far as our information goes, of three men—a Resident, a Senior, and a Junior, all of whom serve on both the medical and the surgical division. The hospital is reputed to have an excellent surgical service.

State Emigrant Refuge and Hospital.—This institution is under the control of the Commissioners of Emigration of the State of New York, by whom all appointments are made. For several years past its administration has differed materially from that of most hospitals, in that there has been no attending staff, but only a Physician-in-chief (who is provided with a house, servants, fuel, etc., and receives a salary of \$1,500 a year) and a Resident Staff of four Assistant Physicians, each of whom is paid \$1,200 a year. Vacancies occur only by resignation or by removal for cause. There is no competitive examination, but the present Board of Commissioners insist that an applicant must have had previous hospital experience, and that he must be able to speak some foreign language fluently, especially German. The duties of the Resident Staff are exceptional, in that they have the charge of, and the responsibility for, the management of the patients in the wards, subject only to the Physician-in-chief.

The opportunities for clinical study afforded in this hospital are of the finest, as regards the number, the variety, and the interesting character of the acute cases under observation. The duties of one of the Assistants are confined to the lunatic asylum, where there are about two hundred patients. All surgical work is required to be done under the direct supervision of the Physician-in-chief, and in capital cases the advice of a member of the Consulting Board may be called for. At present that board is composed of three physicians (Dr. S. O. Vanderpoel, Dr. E. G. Janeway, and Dr. J. W. McLane) and three surgeons (Dr. H. Knapp, Dr. D. M. Stimson, and Dr. W. S. Halsted). The obstetrical service is quite large. The present Commissioners of Emigration are: Henry A. Hurlbut, President; Henry J. Jackson, Secretary; George J. Forrest, Edmund Stephenson, George Starr, Charles F. Ulrich, Charles N. Taintor, the Mayor of New York, the President of the Irish Emigrant Society, and the President of the German Society.

Colored Home and Hospital.—A House Physician and an Assistant serve one year each, six months in each grade. There is no formal examination. The appointment lies with the Attending Physician, Dr.

G. G. Wheelock, 75 Park Avenue, to whom application should be made. The patients are mostly affected with chronic diseases, but there is a fair amount of surgery and midwifery, as well as a good deal of venereal practice.

Randall's Island Hospital.—The service on Randall's Island is limited to the Infants' Hospital, it may be stated that it includes also the Children's Hospital, the Adult Hospital, the Idiot and Epileptic Asylum, and a branch of the City Lunatic Asylum. The term of service is eighteen months, and the members of the staff reside on the island during the whole of that time. They are required to be graduates, to furnish satisfactory credentials of moral character, and to be of good repute. The examining board consists of Dr. Franz Heuel, Jr., Chairman, 33 Irving Place; Dr. E. A. Maxwell, 207 East Fifth Street; Dr. Francis Valk, 233 East Thirty-fifth Street; and Dr. J. L. Perry, 102 West Forty-eighth Street. As a rule, the examinations are held at the Chairman's house. Application may be made to any member of the examining board, or to Dr. J. P. Munn, Secretary of the Medical Board, 50 East Thirty-first Street. Two vacancies are to be filled the 1st of April, and the examination will probably be held some time in the last week in March. Medical graduates do not seem to be generally aware of the value of this service; when it is better known, it will doubtless be more sought after.

Nursery and Child's Hospital.—The house staff consists of one House Physician and one Assistant House Physician, the term of service being six months in each grade, one year in all, and both reside in the house during the entire term. Vacancies occur the 1st of June and the 1st of December, competitive examinations being held about ten days prior to those dates. Applicants must be graduates in medicine, and their character as gentlemen must be well attested. Other things being equal, those who have had previous hospital experience are preferred. The hospital affords excellent opportunities for the study of obstetrics and the diseases of children. About two hundred and forty cases of labor occur annually, chiefly among primiparae, and about seven hundred children are inmates for a longer or shorter time each year. As some women are admitted with their children after confinement, the entire number of adults cared for during the year is about four hundred and fifty. The opportunities for the study of diseases of children are exceptionally good. No children over four years of age are retained in the institution.

Woman's Hospital.—The house staff consists of two House Surgeons, two Seniors, and two Juniors, all of whom, except the Juniors, reside in the house during their entire term of service (eighteen months in all, six months in each grade), except when the institution is closed, as it is every summer from the 1st of July to about the middle of September. Appointments are made on the 1st of April and the 1st of October, the examinations being held at the hospital on the last Wednesday in March and September. Application should be made to Dr. James B. Hunter, Secretary of the Medical Board, 2 East Thirty-third Street. One of the House Surgeons has charge of the executive work of the medical service—attending to correspondence, the admission of patients, and the control of the nurses. The Attending Surgeons, five in number, have a continuous service—three on one division, and two on the other; each house staff serves first on one division and then on the other, changing once in six months. The practice of the house is entirely gynecological, and very largely operative. Nowhere else in America is there so good an opportunity to observe abdominal surgery, and in no other place in the world can more be learned in general gynecological surgery.

Women's Hospital.—The term of service is two years. The next vacancy occurs November 1, 1884. The last appointment was made after a competitive examination, but practically the Executive Surgeon has the sole appointing power. The appointments consist of a House Surgeon, a Senior, a Junior, a private room, and board.

Women's Hospital.—The term of service is one year, but it is sometimes extended to two years. The appointments consist of a House Surgeon, a Senior, a Junior, a private room, and board. The House Surgeon resides in the hospital, but has no salary. It is intended to give him an Assistant very soon.

SANITARY APPOINTMENTS.—The Board of Health employs about twenty regular Sanitary Inspectors, each of whom is paid \$1,550 a year. The salary is the chief attraction, as the duties are monotonous, somewhat exacting, and not often interesting. Nevertheless, there are hundreds of applicants now on the list. The appointments are made by the Health Commissioners, consisting of the Health Officer of the port and the President of the Board of Police Commissioners, *ex-officio*, and Professor Charles F. Chandler and Dr. Woolsey Johnson. Besides the Sanitary Inspectors, there is a Vaccinating Corps, varying from five to ten in number, each man being paid \$1,200 a year. When a vacancy occurs in the corps of Sanitary Inspectors, it is usually filled from the Vaccinating Corps. Every summer an auxiliary corps is employed for a few weeks, consisting of from fifty to a hundred men, each of whom is paid at the rate of \$100 a month. Their duties are to visit the inmates of tenement-houses and prescribe for the sick poor.

AN ARMY MEDICAL EXAMINING BOARD has been ordered to assemble at the Army Building, corner of Houston and Greene Streets, New York City, New York, March 1, 1893, for the examination of such persons as may be properly invited to present themselves before it as candidates for appointment in the Medical Corps of the army, and will probably continue in session about three months.

All candidates for appointment in the Medical Corps must apply to the Secretary of War for an invitation to appear for examination. The application must be in the handwriting of the applicant, must state date and place of his birth, and place and State of which he is a permanent resident, and must be accompanied by certificates based on personal acquaintance from at least two persons of repute as to citizenship, character, and moral habits; testimonials as to professional standing from professors of the medical college at which he graduated should also accompany the application, if they can be obtained. The candidate must be between twenty-one and twenty-eight years of age (without any exceptions), and a graduate of a regular medical college, evidence of which, his diploma, must be submitted to the board.

Further information regarding these examinations and the nature thereof can be obtained by addressing the Surgeon-General, United States army, Washington, D. C.

THE MARINE-HOSPITAL SERVICE.—At present there are no vacancies, and the time and place of meeting of an examining board can not now be stated. The board usually meets in Washington. The Civil Service Act of January 16, 1883, is applicable as regards appointments, promotions, and removals of medical officers. The compensation of Surgeons is at the rate of \$2,500 per annum; that of Passed Assistant Surgeons, \$1,800; and that of Assistant Surgeons, \$1,600. Candidates, in presenting their applications for examination, should state their age, the medical school or college of which they are graduates, and furnish testimonials from at least two persons as to their professional and moral character.

The Supervising Surgeon-General has published the following extract from the regulations of the service for the information of candidates:

"24. Original appointments of medical officers in the United States Marine-Hospital Service will be made to the grade of Assistant Surgeon only.

"25. Medical officers in the Marine-Hospital Service will in no case be appointed to any particular station, but to the general service, being subject to change of station as the exigencies of the service may require, and shall serve in any part of the United States wherever assigned to duty by the Secretary of the Treasury.

"26. No person will be appointed an Assistant Surgeon whose age is less than twenty-one or more than thirty years, and, as a preliminary to a recommendation for appointment, the applicant must have graduated in medicine at some respectable medical college, and must pass a satisfactory physical and professional examination before a board of surgeons of the Marine-Hospital Service, which will be convened from time to time, for that purpose, by the Secretary of the Treasury.

"27. The passing of an examination must not be considered as giving assurance of appointment, as the department will select those of the highest attainments in case there should be more candidates than vacancies.

"28. No qualified candidate will be eligible for appointment more than one year. If not appointed within that time, he may, if he desires, be re-examined, when, if successful, he will take position with the class last examined.

"29. An applicant failing at one examination may be allowed a second examination, after one year, but not a third.

"30. Assistant Surgeons, after three years' service, at least one year of which shall have been at a United States Marine Hospital, shall be entitled to an examination for promotion to the grade of Passed Assistant Surgeon. The application for this examination must be accompanied with testimonials of correct deportment and habits of industry from the Surgeons with whom they have served, and the applicant must be familiar with these regulations.

"31. A vacancy in the grade of Surgeon will be filled by promotion from among the Passed Assistant Surgeons."

We quote as follows from the Annual Report of the Supervising Surgeon-General for the year 1880:

"There is probably no branch of the public service to which the rules laid down by the Civil-Service Regulations of 1872 can be more easily applied. The experience of this office has not only demonstrated their practicability, but has proved entirely satisfactory. The following table shows the number of candidates examined for the past five years:

YEAR.	No. of candidates.	No. of branches in which examined.	Passed.	Rejected.	Percentage of those rejected who failed in the branch examined.	Number invited to appear for examination.
1875	11	10	8	3	27.3	..
1876	13	10	8	5	38.5	..
1877	18	10	6	12	66.7	24
1878	11	10	3	8	72.7	35
1879	29	10	6	23	79.3	52
1880	33	10	4	19	82.3	43

* One of these candidates was appointed Assistant Surgeon, notwithstanding his failure to pass the Board of Examiners. No other instance of the kind has since occurred, and the person thus appointed is not now in the service.

"The marking adopted has been in accordance with the scale recommended by the Board of Civil-Service Examiners of the Treasury Department in their report, dated January 21, 1873.

"The scale is as follows:

Best possible	100
Extremely good	90
Very good	80
Good	70
Somewhat good	60
Indifferent	50
Somewhat bad	40
Bad	30
Very bad	20
Extremely bad	10
Worst possible	0

"In an average examination, the only branch in which the 'best possible' may be obtained is, of course, anatomy, but it may be occasionally reached in the answers to certain questions in several branches. In the first four years during which these examinations were held, no examination in the common-school branches was made, but during the last year an oral examination in arithmetic, physics, and history has been added. Proficiency in these branches, together with a 'personal history' showing the candidate to have had good advantages in schools or experience in hospitals, increases the marking under the heading 'general aptitude.' This heading is the one most likely to be misinterpreted by the enemies to the system, or by the friends of disappointed candidates, and yet it has been found impracticable to discontinue it. Under this heading are included the preliminary education of the candidate, his health, his personal appearance as to neatness or slovenliness, as well as the general fitness for the service, as shown by examination papers as a whole.

"The following is given as a specimen of the examination papers,

and shows the scope of the examination. The questions were propounded at the session of the board held in April, 1879:

"*Anatomy*.—1. Name the bones of the cranium, the foramina at its base, and the structures transmitted through them. 2. Give the origin and distribution of the trigeminal nerve. 3. Describe the regions of the abdomen, and name the viscera contained in each. 4. Name the parts divided in a circular amputation of thigh at middle of Scarpa's triangle.

"*Physiology*.—1. Give the histology and function of the kidneys. 2. How is the nutrition of muscular tissue effected? 3. Give the normal constituents of bile, blood, and gastric juice. 4. Give functions of sympathetic system and spinal cord.

"*Chemistry*.—1. Describe the atom and molecule, and state what is meant by atomic weight and molecular weight of element. 2. Give the chemical reaction that occurs in an active galvanic battery composed of carbon and zinc plates, and the fluid made by dissolving bichromate of potassium in dilute sulphuric acid. 3. Describe the physical and chemical properties of alum, and give its formula. 4. Mention the different forms of carbon, and give brief description of each, and name the most important combinations of this element.

"*Practice of Medicine*.—1. Describe the process of inflammation. 2. Give briefly the symptoms and treatment of cerebro-spinal fever. 3. What are the causes of anasarca? 4. Give differential diagnosis between *eczema*, *herpes*, *cupul*.

"*Hygiene*.—1. Give briefly your views as to the best method of lighting, heating, and ventilating hospital wards. 2. Assuming that the water supply of a hospital contains matters deleterious to health, what method would you use to discover the impurities, and to eliminate them? 3. What, in your opinion, are the necessary articles, and proper proportions of the same, for a hospitalization? 4. What are the principal substances used as disinfectants and deodorizers, and what is their mode of action?

"*Surgery*.—1. Give the causes of compression and concussion of the brain, and their differential diagnosis and treatment. 2. What are the causes of popliteal aneurism? 3. Describe the treatment of compound comminuted fracture of the leg. Give the best method of management, and the possible dangers of the injury. 4. Mention the symptoms, complications, and treatment of penetrating wounds of the chest and of the abdomen.

"*Obstetrics*.—1. Describe the fetal circulation, and the changes taking place therein, at birth. 2. Give the causes and treatment of post-partum hemorrhage. 3. Give the causes, symptoms, and treatment of puerperal convulsions. 4. Give the differential diagnosis between abdominal tumors, spurious and true pregnancy.

"One day is devoted to clinical examinations at a hospital; which, with an oral examination, concludes the exercises."

DEATH FROM CHLORAL.—"The British Medical Journal" records another death through the careless self-administration of hydrate of chloral. The victim was the widow of an admiral in the navy. The servant who accompanied her home from the house of a friend saw her place a bottle on the mantel-shelf, at the same time exclaiming, "I am dying; I have taken fourteen doses!" The preparation was found to be a patent medicine known as "Hunter's Solution of Chloral." There was no evidence of premeditated suicide. In addition to the verdict of accidental death the coroner's jury recommended that restrictions should be placed upon the sale of patent medicines that may be used as poisons.

THE MORTALITY REFERABLE TO ALCOHOL.—At the end of a long and carefully prepared report recently drawn up by a Committee of the Harveian Society, it is concluded that there is, upon the whole, reason to think that, in the metropolis, the mortality among any considerable group of intemperate persons will differ from that generally prevailing among adults in the following important particulars: viz., a fourfold increase in the deaths from diseases of the liver and chylotropic viscera; a twofold increase in the deaths from disease of the kidney, a decrease of half as much again in those from heart disease, a marked increase in those from pneumonia and pleurisy, a considerable increase in the earlier occurrence of those from disease of the central nervous system; a marked decrease in those from bronchitis, asthma, emphysema,

and congestion of the lungs; a marked increase in the earlier occurrence of phthisis, and a later occurrence, or at least termination, of the disease; a very large decrease in those from old age, with an increase in those referred to atrophy, debility, etc., and the addition of a considerable group referred in general terms to alcoholism or chronic alcoholism, or resulting from accidents.—*Lancet & M. J.*

SILARING OR MOLDING OF THE FETAL HEAD.—Dr. W. J. Simpson ("Edinb. Med. Jour.," Dec., 1882, p. 515) states that the ordinary shape of the fetal head while in the uterus is ovoid. This is ascertained from Cæsarean sections, and from breech deliveries, when the head is only a short time in the pelvis, and is not subjected to pressure for a long period of time. The changes which occur in the shape of the head after face and head presentations are due to alterations in the relations of the bones to one another, and are, therefore, additional to what may be produced by the ordinary caput succedaneum. Hence, examination of the head will enable one to say whether the cephalic or the pelvic end of the child was born first. The following propositions are submitted: 1. That in the configuration of the fetal head certain information may be gained concerning the labor which may be useful in confirming or refuting the statements of the accoucheur, and in enabling the medical jurist to arrive at an opinion as to the probable cause of death, where the lung has been partially expanded. 2. That no medical report on a newly born child is complete which does not state the external form and appearances of the head, with special bearing on the moldings it has undergone during the labor.

EPIDEMIC AND THE CLOSURE OF SCHOOLS.—The paper read before the British Medical Association ("Brit. Med. Jour.," Sept. 30, 1882), Dr. H. Page speaks of public and private schools as centers of infection during the prevalence of zymotic diseases, and states that experience has shown that the great preventive measure consists in their closure. An illustration of this is given in the case of an epidemic of scarlet fever which appeared in a certain English parochial district in 1878. From its outbreak to its termination the following facts were elicited: Before the closure of the public elementary schools there were, of known new cases 121, of infected houses 86, of deaths 26. During the period of closure there were, of known new cases 36, of infected houses 34, of deaths 13. After reopening there were, of known new cases 143, of infected houses 84, of deaths 45. The schools were closed only one month, and at the end of that time the health officer was unable to obtain an extension. The effect of reopening too soon is apparent. He proposes to place on a permanent basis the system of footing, by an amended health act, and a reorganization of the sanitary service, upon the following basis. [The principles will apply equally well to all countries.] 1. That school (and all other) health matters be under the jurisdiction of the Health Department and local sanitary authorities only. 2. That universal notification of the seven principal zymotics, to the medical officer of health, be compulsory on the part of both the medical attendant and the householder. 3. That the closure of schools be compulsory when they are acting as centers of infection. 4. That provision of hospitals for infectious diseases be compulsory. 5. That persons suffering from infectious diseases must be removed thereto from houses in which effective isolation is impossible.

A FAVORABLE REPORT ON THE USE OF POTASSIUM IODIDE.—A solution of iodine in potassium iodide. Mr. H. H. Croft has tested some of the poison itself with this solution, and finds that a light brown amorphous precipitate is formed, the insolubility of which explains the beneficial action of the antidote. When iodine can not be readily obtained, a solution of potassium iodide, to which a few drops of ferrous chloride has been added, may be used, and will be found to be of service.—*Lancet.*

QUINIDINE.—Kassab & May's "Quinid" is a new preparation. "The Quinologist," is always preferred by all druggists who sell the article by the drachm or half-drachm at the counter, as it is so bulky that a drachm looks to the buyer like twice the quantity.

DR. ALEXANDER OSBORN'S NEW METHOD OF TREATING GOUT.—It has been reported to the Council of the Royal Society, that Dr. Osborn's

THE HAMMOND PRIZE.—The American Neurological Association offers a prize of five hundred dollars, to be known as the "William A. Hammond Prize," and to be awarded at the meeting in June, 1884, to the author of the best essay on the "Functions of the Thalamus in Man."

The conditions under which this prize is to be awarded are as follows:

1. The prize is open to competitors of all nationalities.
2. The essays are to be based upon original observations and experiments on man and the lower animals.
3. The competing essays must be written in the English, French, or German language: if in the last, the manuscript is to be in the Italian handwriting.
4. Essays are to be sent (postage prepaid) to the Secretary of the Prize Committee, Dr. E. C. Seguin, 41 West Twentieth Street, New York City, on or before February 1, 1884; each essay to be marked by a distinctive device or motto, and accompanied by a sealed envelope bearing the same device or motto, and containing the author's visiting-card.
5. The successful essay will be the property of the association, which will assume the care of its publication.
6. Any intimation tending to reveal the authorship of any of the essays submitted, whether directly or indirectly conveyed to the committee or to any person thereof, shall exclude the essay from competition.
7. The award of the prize will be announced by the undersigned committee, and will be publicly declared by the President of the association at the meeting in June, 1884.
8. The amount of the prize will be given to the successful competitor in gold coin of the United States, or, if he prefer it, in the shape of a gold medal bearing a suitable device and inscription.

Signed, { F. T. MILES, M. D., Baltimore,
J. S. JEWELL, M. D., Chicago,
E. C. SEGUIN, M. D., New York.

THE POLYCLINIC.—One hundred and two physicians were studying in the various classes at the New York Polyclinic within the first three months of its existence, and over two thousand patients had been presented to them for examination and treatment.

A RECEPTION TO THE PRESIDENT AND VICE-PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.—Dr. John V. Shoemaker, the editor of the "Medical Bulletin," lately gave a reception at his house, in Philadelphia, in honor of Dr. John L. Atlee, of Lancaster, Pa., and Dr. Alexander G. Stone, of St. Paul, Minn., the former the President and the latter the Vice-President of the American Medical Association. A great number of well-known members of the profession were present, not only from Pennsylvania, but from several of the neighboring States, and the affair is said to have been very brilliant.

DEATH OF DR. LAFAYETTE RANNEY.—On the 15th inst. Dr. Lafayette Ranney died, in consequence of a renal affection, in the sixty-fourth year of his age. Dr. Ranney was graduated at the Medical Department of Dartmouth College in the year 1846. For many years he had been a practitioner in New York. He was formerly connected with the medical department of the police service, and was highly esteemed by the legal profession as an adviser in matters involving medical questions.

ARMY INTELLIGENCE.—*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 10, 1883, to February 17, 1883.*—BROWN, JOSEPH B., Lieutenant-Colonel and Surgeon. Detailed as member of board for examination of assistant surgeons for promotion and candidates for admission into the Medical Corps, U. S. Army, to convene at New York City on March 1, 1883. Par. 1, S. O. 35, A. G. O., February 10, 1883. — CLEMENTS, BENNETT A., Major and Surgeon. Detailed as member of board for examination of assistant surgeons for promotion and candidates for admission into the Medical Corps, U. S. Army, to convene at New York City on March 1, 1883. Par. 1, S. O. 35, A. G. O., February 10, 1883. — JANEWAY, JOHN H., Major and Surgeon. Detailed as member of board for examination of assistant surgeons

for promotion and candidates for admission into the Medical Corps, U. S. Army, to convene at New York City on March 1, 1883. Par. 1, S. O. 35, A. G. O., February 10, 1883. — TOWN, FRANCIS L., Major and Surgeon, is relieved from duty at Fort Walla Walla, and will report to the commanding officer, Vancouver Barracks, for duty as Post Surgeon. S. O. 7, Department of the Columbia, January 27, 1883. — WOODWARD, J. J., Major and Surgeon. The extension of leave of absence on account of sickness granted October 6, 1882, is further extended six months on account of sickness. Par. 9, S. O. 34, A. G. O., February 9, 1883. — DE LOFFRE, AUGUSTUS A., Captain and Assistant Surgeon. Relieved from further duty in this department. S. O. 28, Department of the Missouri, February 5, 1883. — NEWTON, R. C., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Cummings, New Mexico, and will proceed Fort Sill, Indian Territory, and report to the commanding officer for duty. S. O. 28, Department of the Missouri, February 5, 1883.

OFFICERS OF THE MARINE-HOSPITAL SERVICE.—The following official list of medical officers and acting assistant surgeons of the United States Marine-Hospital Service, with their stations, February 1, 1883, has been furnished by the Treasury Department: *Supervising Surgeon-General*—John B. Hamilton, Washington, D. C. *Surgeons*—P. H. Bailhache, Washington, D. C.; John Vansant, San Francisco, Cal.; W. H. H. Hutton, Louisville, Ky.; T. W. Miller, Chicago, Ill.; Walter Wyman, Baltimore, Md.; W. H. Long, Detroit, Mich.; R. D. Murray, Memphis, Tenn.; * C. S. D. Fessenden, St. Louis, Mo.; George Purviance, Boston, Mass.; H. W. Sawtelle, New York, N. Y.; H. W. Austin, Cincinnati, Ohio; J. M. Gassaway, Philadelphia, Pa.; Henry Smith, Norfolk, Va. *Passed Assistant Surgeons*—G. W. Stoner, Portland, Maine; J. C. Fisher, Washington, D. C.; John Godfrey, New Orleans, La.; C. B. Goldsborough, Mobile, Ala.; Fairfax Irwin, Wilmington, N. C.; F. W. Mead, Port Townsend, W. T.; H. P. Cooke, Galveston, Texas; H. R. Carter, Memphis, Tenn.; † W. H. Heath, Buffalo, N. Y. *F. D. Porter, Charleston, S. C. Assistant Surgeons*—F. J. O'Connor, Detroit, Mich.; John Gutiérrez, Key West, Fla.; W. A. Wheeler, Chicago, Ill.; J. A. Benson, Cairo, Ill.; C. E. Bangs, Portland, Oregon; D. A. Carmichael, Pittsburg, Pa.; S. T. Armstrong, New Orleans, La.; P. H. Bennett, Boston, Mass.; C. T. Peckham, New York, N. Y.; R. P. M. Ames, Evansville, Ind.; S. C. Devan, San Francisco, Cal.; F. M. Urquhart, St. Louis, Mo.; P. C. Kallouch, New York, N. Y.; H. W. Yennans, Sitka, Alaska. *Surgeons (retired)*—T. J. Griffiths, † Louisville, Ky. *Acting Assistant Surgeons*—J. M. Allen, Milwaukee, Wis.; W. A. Banks, Rockland, Maine; H. G. Bates, Newbern, N. C.; B. F. Beebe, Cincinnati, Ohio; A. D. Bevan, Chicago, Ill.; R. D. Bibber, Bath, Maine; J. E. Bready, Dubuque, Iowa; J. B. Brewster, Plymouth Mass.; G. B. Case, Cleveland, Ohio; S. B. Conover, Philadelphia, Pa.; W. A. Cox, Pascagoula, Miss.; Byron DeWitt, Oswego, N. Y.; A. W. Fisher, Toledo, Ohio; J. P. C. Foster, New Haven, Conn.; T. L. Gelzer, Escanaba, Mich.; L. P. Gibson, Little Rock, Ark.; A. H. Glennan, Baltimore, Md.; W. M. Griffiths, Louisville, Ky.; A. C. Hamlin, Bangor, Maine; G. A. Harding, Sault Ste. Marie, Mich.; W. H. Heard, Newport, Ark.; B. S. Herndon, Fredericksburg, Va.; H. S. Hersey, Bismarck, Dak.; R. C. Hodges, Indianola, Texas; L. W. Hodgkins, Ellsworth, Maine; S. B. Hunter, Machias, Maine; R. W. Johnson, Baltimore, Md.; J. M. Kercheval, Nashville, Tenn.; Samuel Kitchen, East Saginaw, Mich.; H. E. Mereness, Albany, N. Y.; J. D. Mitchell, Jacksonville, Fla.; P. H. C. Noble, Richmond, Va.; Charles Otilie, La Crosse, Wis.; T. T. Price, Tuckerton, N. J.; S. D. Robbins, Vicksburg, Miss.; S. H. Sears, Newport, R. I.; Elmer Small, Belfast, Maine; W. N. Smart, Grand Haven, Mich.; A. E. Spohn, Corpus Christi, Texas; J. G. Stanton, New London, Conn.; Theodore Starbuck, Ferdinand, Fla.; W. D. Stewart, Vineyard Haven, Mass.; J. M. Stuart, San Francisco, Cal.; G. H. Stone, Savannah, Ga.; D. H. Strickland, Erie, Pa.; Joseph Taylor, Shreveport, La.; W. H. Taylor, New Bedford, Mass.; A. S. Tebbis, Marquette, Mich.; J. V. Vandeman, Chattanooga, Tenn.; R. F. Wentworth, Portsmouth, N. H.; C. A. Lectures and Addresses.

AN ABSTRACT OF

THE PRESIDENT'S ADDRESS,

DELIVERED BEFORE THE NEW YORK ACADEMY OF MEDICINE,
FEBRUARY 1, 1883.

By FORDYCE BARKER, M.D., LL.D., ETC.

(Concluded from page 198.)

The discussion of the papers is free and open to all, but the time of the Academy is too valuable to be taken up in listening to the crude, impulsive, badly arranged outbursts of the moment. In these discussions we wish to bring out those who are competent to give us the result of their careful study, their mature experience and deliberate judgment, those who have formed distinct opinions, and can clearly state the mental processes by which they have arrived at their opinions. Partly to prevent waste of time, but chiefly to secure discussions of a high character, I have been in the habit of calling upon those whom I have believed, from the character which they had acquired in the profession, to be the most competent to add something to the knowledge and thought of the special topic of the evening. But I am fully aware of the objections and difficulties which may be urged against this course, and shall be most thankful to any one who will suggest improvement on this plan. One objection of great force is that it is impossible for any one to know, either personally or by reputation, all who are specially qualified, and false modesty may prevent some who would add greatly to the interest of the discussion, because they are not called out by the Chair. This would be particularly liable to occur in the case of young men, who have not yet had the opportunity to make themselves known to the profession, but who might be far in advance of the elder speakers in knowledge of the subject of the evening, as the latter are engaged in active practice, and may not have had time to keep up with the rapid progress in all departments of medicine. My own experience has been that from this class I learn the most; it is from them that I get the most useful knowledge and the most valuable suggestions. I hold it to be one of the great missions of this Academy to bring out and develop, by its library and its scientific work, the young men who are to take care of its interest and give the stamp of character to the Academy and the medical profession of this city in the future. I do not hesitate to express the belief, based on a rather extensive acquaintance with the profession in other cities and in other countries, that the number of young men of bright intellects, of noble zeal, who have had the largest opportunities at home and abroad for a thorough and complete education, which have been most conscientiously improved, is greater than has ever before been aggregated in any city in any age of the world, and that twenty years hence New York will have a galaxy of distinguished men who will give the medical profession such prominence with the public and with the profession elsewhere as has never before been attained. Some weeks ago I had a paragraph printed on our notice cards, asking that

any one willing to take part in the discussion of the paper to be read before the Academy would kindly send me a note, giving his name. This would insure his being called up by the Chair, and would relieve him from the embarrassment of modesty. Still, I wish it distinctly understood that those competent to speak to edification will always be gladly listened to, even though the Chair, from ignorance or oversight, fails to call them out.

The mental activity of the profession in this city has been wonderfully developed, and its contributions to our literature have wonderfully increased, since the organization of the Academy. The number of medical works by New York authors in the fifty years from 1800 to 1850 was 109. In the ten years from 1850 to 1860 New York writers published 65 medical works. From 1860 to 1870 the number was 69, and from 1870 to 1880 the number is 102, the whole number in the last thirty years being 236. To this it should be added that New York writers have also, in this period of thirty years, contributed, according to the most accurate estimates that I can obtain, at least 25,000 pages to the periodical medical literature of the country.

I think that we have no cause for anxiety in regard to the scientific work of the Academy in the future. But the great need of the Academy, in order that its full mission may be accomplished, is that it should be placed on such a financial basis as will secure it the means of doing all its important work in preserving its library by binding, which is absolutely necessary for the preservation of its periodical literature, and the thousands of precious pamphlets absolutely essential, that the profession may have ready access to its complete literature on every topic pertaining to medicine in all its branches, keeping up our circulating and journal department to the requirements of the present high standard, and meeting the demands of the future. The profession have contributed so liberally, in proportion to their means, within the past four years, to accomplish what has already been done, which is equally of benefit to the public and to the profession, that I have not the assurance at present to ask for more for this purpose, as I feel well assured that it will be voluntarily offered as duty prompts and circumstances will permit. But I do ask all to join in hearty co-operation to secure the necessary addition to our funds during the present year to make certain the accomplishment of the foregoing important ends. No city has a greater accumulation of individual wealth than New York; none has greater liberality when properly appealed to, and the intelligence and judgment are convinced of the justice and necessity of the appeal. This has been amply shown in its liberal provision of hospital accommodation for the sick poor, and in numerous other directions. But it has done little for the profession on which it relies for the preservation of its health and lives, and I am convinced that this is simply because the necessity and motives for giving such aid have never been laid before it. Its liberality has consequently never taken this direction. In the continental countries of Europe such an organization as ours would be effectively assisted by appropriations from the State. In Great Britain it would be stimulated to active work and

aided by liberal contributions from private individuals. Some of us have seen the noble hall of the Royal College of Physicians in London, and read with a thrill of interest the tablets on its walls, which commemorate the names of noblemen, commoners, and physicians who have contributed large sums for the purpose of building the hall and placing the college on a solid financial basis. The comparatively small city of Edinburgh, which does not hold even a secondary position as a place of wealth and commerce, ranks, as a city of literary and scientific ability, of eminence in the learned professions of divinity, medicine, and law, and of educational advantages, as one of the first in the world. Last summer I visited its new infirmary, an immense pile of buildings of considerable architectural merit, in which the famous medical department of the university finds a home, with every convenience as to room and equipment which a school of such rank demands at the present day to keep up its former prestige and reputation. It is not yet quite finished, but the sum already expended, if I am not mistaken, is now more than a million of dollars, all of which has been voluntarily contributed by the public-spirited citizens of Scotland. In New York, medical colleges are built, owned, and supported by its profession, and receive no aid from the public, except when an equivalent in the form of a mortgage is returned. The most enthusiastic admirers of Boston do not profess to believe that it is a larger city, or that it has more wealth, or more liberality, or more public spirit than New York. Yet the new building of the medical department of Harvard University is now rapidly approaching its completion, the most expensive and the most perfect of its kind that has yet been built in this country, at a cost, including the land, of nearly three hundred thousand dollars, contributed by private individuals. All this is for the advantage of elementary medical education. Can any one doubt that, if the matter was properly and judiciously brought to their notice, there are many of our citizens who would be glad of the opportunity to give the requisite sum for the higher purposes of this Academy to place it on such a financial basis as would enable it to carry out effectually all its noble purposes. In looking over the "Annuaire de l'Académie de Médecine" of Paris, I find that ten of its pages are filled with an account of the bequests that the institution has received. The copy which I have is for the year 1876, and I find that the amount of legacies which it has received from the date of the organization of this academy to that year is over fifty-six thousand dollars. Some of the donors were medical men, others were laymen, and some ladies appear in the number. I would suggest that hereafter, in our publication of the charter, constitution and by-laws, and list of Fellows, the names of our benefactors and a list of all bequests should appear, that thus they may be kept in perpetual memory by the Fellows of the Academy.

In conclusion, may I express the hope that we feel that our duty to the Academy is a duty that we owe to our profession, that its prosperity and usefulness, and its good and active work, may continue to advance, and that the motto of our loving cup may always be a controlling sentiment with us, "May peace and love be multiplied unto us."

ABSTRACT OF THE CARTWRIGHT LECTURES ON THE RELATIONS OF MICRO-ORGANISMS TO DISEASE.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK,

BY WILLIAM T. BELFIELD, M. D.,

CHICAGO.

LECTURE I.

(Concluded from page 199.)

It seemed to the author that the substitution for this method of one which he would proceed to describe would hasten the solution of many problems now involved in obscurity, and would tend to avoid much confusion which at present existed with regard to this subject. The only means by which an organism in a culture could be shown positively to be the progeny of that which had first been transplanted was, that it must have been observed to proceed from it by continuity of structure, and this could only be done by direct observation under the microscope. The method to which he alluded was that introduced three years ago by Koch, and consisted in the substitution, for a liquid vehicle for the nutrition and cultivation of the organism, of a solid material. A solution of gelatin, or beef extract, or peptone, or other material, according to the species of bacteria which it was desired to cultivate, was sterilized and spread upon a disinfected slide, and allowed to dry. A heated needle was then dipped into the material containing the bacteria and drawn lightly over the substance upon the slide, by which a scratch was made, to the edges of which the bacteria adhered. The slides were then placed in the incubator. The liabilities to error in this method consisted in the difficulty of thoroughly sterilizing the culture solid, and the danger of other organisms being planted with the one experimented upon. But by this means it was possible to observe the growth by continuity of the organism in successive cultures, in transferring it to a second and a third slide, and so on, multiplying it indefinitely. By this method alone were we able to demonstrate that an organism injected into an animal from the tenth or the hundredth culture was structurally the same as the organism taken from the animal which had suffered from the disease in which the original bacterium had been found.

Dr. Belfield then described the method of observing the bacteria under the microscope, and the best instruments for that purpose.

Before discussing the relation of bacteria to the body in disease, the speaker referred to their relations to the animal in health and after death. It had been a widely disputed question as to whether bacteria ever occurred in the animal in a perfectly healthy state, the affirmative view having been taken by Billroth and some others, but it was denied by Koch, by Pasteur, and by Ehrlich, who stated that they had never detected bacteria in the healthy animal. The failure of putrefactive bacteria to reproduce themselves in healthy tissue, according to experiments referred to, would go to show inability to struggle against the normal cells indigenous to the soil upon which they were planted. Some bacteria showed power of existence only in tissue in which

vitality had entirely ceased, while others seemed to possess the power of existence in the presence of the animal cells when the latter suffered from impairment of nutrition and the tide of life was turning against them. Abnormal composition of the blood seemed to favor the development of some bacteria after they had found their way into the tissues. An illustration of this fact was seen in diabetes, where there was a tendency to the formation of abscesses, carbuncles, etc., which were found to contain micrococci in abundance.

Dr. Belfield then discussed the question as to the possibility of the bacteria gaining access to the system except by way of solution of continuity of tissue, and reached the conclusion that the answer depended at the present time altogether upon what might be considered a solution of continuity of tissue; certainly a gross lesion, one sufficiently large to strike the attention of the naked eye, was not required. This was also evident in the case of other animals, as the trichina, which found its way from the intestine into the muscles. Any one familiar with the structure of the alveoli of the lungs could readily conceive how such small particles as bacteria could with facility gain access to the circulation in those organs.

One of the most important questions in pathology at the present day was with respect to what extent the different species of bacteria which were to be found in the human tissues during certain morbid conditions were to be considered the cause of the conditions with which they were respectively associated. Admitting the causal relation of the bacterium to the disease, we must be convinced, the speaker said, that all the observed phenomena could be reconciled with this assumption, and also that they could not be so plausibly explained by any other assumption. Then the assumption must be demonstrated by successive cultures of the bacteria found to exist in the diseased person, and the induction of the same disease in healthy animals by inoculation with a reproduction of the bacteria. According to this standard, the evidence already brought forward warranted the following unscientific, but convenient classification:

First, diseases the demonstration of the bacterial origin of which had been completed through inoculation with isolated bacteria by competent observers.

Second, diseases the bacterial origin of which had been affirmed after inoculation with isolated bacteria by one competent observer; such as tuberculosis.

Third, diseases which were always characterized by the presence of bacteria in the tissues, but which had not been induced by inoculation with isolated bacteria; such as pyæmia, diphtheria, erysipelas, etc.

Fourth, diseases in which after death bacteria had been found in the tissues; such as variola, scarlatina, typhoid fever, etc.

Fifth, diseases in which the presence of bacteria before and after death had been asserted, such as syphilis, intermittent fever, typhus fever, measles, etc. In the diseases under the fourth and fifth classes, observations had doubtless been more or less imperfect and inaccurate, partly because of those diseases being found exclusively in man.

Dr. Belfield then exhibited some micro-photographs, in

illustration of the subject under consideration, part of which had been prepared by his own hand, and part obtained from negatives kindly furnished him by Professor Koch.

Original Communications.

TRICHINIASIS IN ITS RELATION TO PUBLIC HEALTH AND NATIONAL ECONOMY.

BY FRANK S. BILLINGS, VET. SURG.

LEWIS, IOWA.

I.

THE time is coming, if not already at hand, when the people of this country, individually as well as collectively, whether represented by local power or by the central Government at Washington, must take some other course than evasion with reference to the contagious, infectious, and invasive diseases of our domestic animals. The promoters of this work must be the veterinarians, and it is to make this as evident as possible that the writer has consented to contribute a series of papers to this journal. If in some way the author appears too prone to polemic writing, and to criticise the action of Government officials, it must be borne in mind that the disease is deeply seated, and nothing but deep excision of the ulcer which disgraces our Government can lay open to the public its full nature.

There is no disease of our domestic animals which more fully illustrates the points which we desire to emphasize than trichinosis of swine, and none which more imperatively demands our attention at present, as shown by the action of the French government a year or so since, and the very recent action of that of Germany, by which American pork is forbidden entrance into that country as an article of food.

Of all the diseases of our domestic animals which bear any relation to the public health, trichinosis of swine enjoys the most sensational reputation, to be exceeded, perhaps, in the not distant future, by tuberculosis of the milch-cow.

According to Heller,* the history of this disease may be divided into three periods, the first beginning with the observation of the capsule of the parasite in the human muscle, the parasite itself not being discovered, in 1821, by Hilton, of Guy's Hospital, London.

The second marks the discovery of the parasite in 1835, and its description by Owen, who gave it its name, trichina spiralis, on account of the position it almost invariably assumes when encapsulated; this period includes that of the establishment of the connection between the disease of man and that of the hog, which took place in 1860.

From 1860 begins the third period, in that of scientific research after the primary cause of the disease; or, in other words, from what source do the hogs chiefly derive the parasite, a question still unsettled, the solution of which we hope is an honor awaiting for some fortunate American observer.

In the mean time it was the fortune of Professor Leidy,

* Von Zoonosen. Hannover, B. 1.

of Philadelphia, to discover the parasite in the muscles of the hog in 1887.

The principal workers in this field of research have been mostly Germans; the names of Owen, Cobbold, Bristowe, and others, of Britain, must not be forgotten, though the chief honors belong to Leuckart, Zenker, Küchenmeister, and the veterinarians Gerlach and Fürstenburg, of Germany.

Cobbold* describes this parasite as follows: "*Trichina spiralis* is an extremely minute nematode helminth, the male, in its fully developed and sexually matured condition, measuring only one eighteenth of an inch, while the perfectly matured female acquires a length of one eighth of an inch; body rounded and filiform, usually found slightly curved on itself, rather thicker in its anterior than posterior portion, especially in males; head narrow, finely pointed, unarmed, with a simple central, minute oval aperture; posterior extremity of the male furnished with a bilobed caudal appendage; the cloacal, or anal aperture, being situated between these divergent appendages; penis consisting of a single spicula, cleft above, so as to assume a V-shaped outline; female stouter than male, bluntly terminating posteriorly, with genital outlet placed forward at about the end of the anterior fifth of long diameter of the body; eggs measuring $\frac{1}{1270}$ of an inch from pole to pole; mode of reproduction, viviparous."

"The shellless ova develop into minute embryos immediately on fructification, completely fill the uterus of the female, and are born in immense numbers. The embryos measure, before birth, about 10 micrometres in length and 5.6 in transverse diameter. The study of the structure of the embryos is almost impossible so long as they are retained within the body of the maternal parasite. Here it resembles a delicate thread having a somewhat granular appearance, which becomes less distinct as development progresses. In the older embryos—extra maternal—we may perceive a very delicate cuticle and an axial line running through the body; the extremities of the body are more or less blunt, and not easily to be distinguished as to which is the anterior and posterior end of the parasite."†

The posterior extremity possesses more rigidity than the anterior, and also seems to possess the ability to move backward and forward. The rigid condition of the anterior terminal end of the embryo corresponds with the situation, or limits of the axial line, which is looked upon as the rudimentary alimentary canal. The anterior portion of the embryo is not granulous, but clear, being only modified by a delicate chitin thread, which is continuous with the cuticle, and constitutes the first indication of the chitinous lining of the oral cavity. As development progresses, this axial line divides into two parts: the anterior portion corresponds to the so called "cell-body" of the mature parasite, and the posterior to the stomach, intestines, etc. The sexual organs can not, as yet, be distinguished. The embryo may be met with, not only in the abdominal cavity of the autosite, but also in the thoracic cavity and pericardial sac, and in

such numbers that these places may be looked upon as normal resting-places of the embryos in their migrations over an infected organism.

In general, we find them far more numerous represented in the abdominal cavity, which exactly corresponds with our knowledge of the activity, for it is here that they must first arrive, after passing the intestinal parasites, on their migrations; from here they pass on to the other cavities by means of the natural openings, osteos, through which the œsophagus and large vessel pass the diaphragm. These vessels are surrounded by loose connective tissue, which offers conditions favorable to the passage of the parasites. From these cavities the embryos follow the course of the large vessels and nerves over the body, the loose connective tissue surrounding them offering favorable conditions to their migration. The duration of the migratory period can not be determined with any positive degree of accuracy, but is undoubtedly very short, as embryos have been found in the thoracic cavity, the pericardial sac, and adjoining muscles as early as in the abdomen. The majority of observers seem to agree in considering the ninth or tenth day of invasion as marking the termination of the migratory period, i. e., when but a single invasion of an organism has taken place. The embryos display no distinguishable changes, either in size or structure, during the periods of migration. The first appreciable changes occur after they have reached the muscles and have become lodged in their fibers.

When they have penetrated the muscle fiber, i. e., become intra-sarcolemmatous, the protoplasm of the fiber undergoes certain pathological changes which exactly correspond to the fatty degeneration observed in parenchymatous myositis. A proliferation of the nuclei is quite common, if not an invariable phenomenon. Like all tissues which have undergone fatty degeneration of their plasma, such fibers are darker, less refracting, than those which have not been subjected to parasitic invasion. Such fibers lose their contractility; when cut transversely, the swollen parenchyma extends beyond the sarcolemmatous sheath; and, if a trichina be near the section, it often extends or becomes free, with the protruded plasma. It is doubtful whether the trichinae live upon the elements of the plasma, as they are, while lodged within the fiber, in an apparently chrysalis condition. This fatty degeneration of the parenchyma seems to offer no impediment to a second invasion of the fiber.

While previous to migration the embryo shows a somewhat slender form, it now assumes a thicker or more rotund form, its transverse diameter being nearly double that which it possessed before migration. Its anterior portion becomes more slender, and resembles that of the mature parasite. The posterior end becomes more blunt. Progressive changes also take place in the axial line, the various organs becoming distinctly marked; especially is this the case in the cell-body. The primitive sexual gland is to be seen as an elongated sac; the pointed anterior end extends beyond the stomach in the females, and turns abruptly backward in the males. The oral cavity has a proportionate length, and over its middle shows distinctly the first traces of a nervous system, which, in the form of an oval enlargement—cer-

* "Entozoa," p. 335.

† Leuckart, "Die menschlichen Parasiten," vol. ii, p. 572.

vical ganglion—is to be distinguished from the cylindrical mass.

With the progressive development of the internal organs a corresponding increase of the external dimensions of the parasite takes place; it increases more in length than thickness, its previous rotund form becoming more slender; at the same time the body becomes curved, and after a while assumes an irregular spiral position—"Trichina spiralis." Those situated in the larger fibers are the first to assume this position, but it occurs in all in course of time, even when the diameter of the fiber scarcely exceeds that of the parasite. The sarcolemmatous sheath of the fiber invariably becomes distended in the vicinity of the parasite. The spindle shape of the tube is due to the elasticity of the sarcolemma; but, as it becomes thicker and clouded, proliferation of its elements must also take place. The intra-sarcolemmatous, or capsular, development of the parasite terminates in about three weeks from the time of the invasion of the fiber.

The distensions of the sarcolemma vary much in form and size; sometimes they are far more cylindrical and elongated than at others, or one end may be elongated and the other obtusely rounded.

The capsules are surrounded by a rete of capillaries, which can be injected; an increase in length and thickness, due to the irritation caused by the parasite, gives them a very ramified character.

In this condition the parasites are known as "muscle trichinæ"; but, when living, or found in the intestines of an autosite, as "intestinal trichinæ." "Muscle trichinæ" have always been said to be confined exclusively to striated or motory muscles, the flesh, and not, in an encapsulated condition, in the non-striated muscles, or in adipose tissue.

With regard to finding trichinæ in adipose tissue, several recent observers report having met with them therein, a fact which I can positively assert to be correct from personal observation, as I found them several times in the midst of the fatty tissue which is to be seen separating the muscle fibers, but never in the adipose tissue which lies upon the muscles; this fact bears an especial relation to the question of trichinæ in the sides of bacon. In a letter, read at the ninth annual meeting of the American Public Health Association, held at Savannah, Georgia, in 1881, emanating from the Department of Agriculture, dated October 29, 1881, the author, with the customary ignorance and consequent impudence of an American politician, says, in answer to the question, "Are trichinæ found in the fat?" "I have until now thought not. Professor Taylor, of this department, tells me that in the Journal of the Microscopical Association he has recently seen that they have been found in fat. I should rather see than believe without so doing."

The finding of an apparently encapsulated trichina, or trichinæ, in inter-muscular fat-tissue seems to me to be perfectly in accordance with known laws or conditions. The trichinæ were, and still are, intra-sarcolemmatous—that is, within the sheath of the originally invaded fiber, which has, however, lost its recognizable characteristics from atrophy and absorption of its plasma, due to the pressure caused by

the infiltration of fat, leaving nothing but its connective elements behind. I think the trichinæ were present anticipatory to production of fact. The atrophy of the fiber is undoubtedly aided by the fatty degeneration of its plasma, caused by the parasite, which has been previously mentioned.

The encapsulated parasites may be met with in the striated musculature of all parts of the body—such as the digital muscles, those of the abdominal walls, of the extremities, the eye, the ear, the larynx and pharynx, the tongue, œsophagus, the diaphragm; but the heart seems to be a favored locality, for they have only been found in its substance in very isolated cases.

In making examinations of œsophageal muscles of a rabbit that had been fed with infected pork, I was much struck with the abruptness with which I found trichinæ, in passing in review a microscopic section of the œsophageo-cardiac portion of the stomach, where one passed from the fibers proper to the stomach to those of the œsophagus; in fact, trichinæ could be seen in striated fibers of the latter where they intruded between the non-striated of the former, but in no case were there any to be seen in the smooth or inorganic fibers.

Trichinæ are not equally distributed over the musculature of an autosite, but seem to have favorite places of abode, such as the muscles of the anterior part of the body; of these, those of the tongue, larynx and pharynx, and masticatory muscles are especially favored. The muscles of the rump are more profusely invaded than those of the extremities. Very few have been found in the caudal appendage of any animal. In the long muscles of the limbs the parasites are found to be more numerously represented where the fibers begin to lose themselves in their tendinous extension than in the body of the muscle. Numerous calculations have been published by different observers as to the percental invasion of the different muscle groups, several of which are here appended:

Microscopic* specimens of an average length of two centimetres and a width of one centimetre were taken from the flesh of several hogs which had been found trichinous.

Eighty specimens from hog No. 1 gave as follows:

a.	Pillars of diaphragm	12 trichinæ
b.	Muscles	4 "
c.	" larynx	1 trichina
d.	" ribs	
e.	" tongue	
f.	" neck	None.
g.	" eye and forearms	

Sixty specimens from hog No. 2:

a.	Pillars of diaphragm	10 trichinæ
b.	Muscles	6 "
c.	" larynx	2 "
d.	" ribs	
e.	" tongue	
f.	" eye	None.
g.	" forearm and neck	

* Mittheilungen d. d. thierärztlichen Praxis im preussischen Staats-
1877-'78, p. 99.

Forty specimens from hog No. 3:

a. Pillars of diaphragm.....	40 trichinæ.
b. Muscles ".....	25 "
c. " " larynx.....	4 "
d. " " ribs.....	6 "
e. " " tongue.....	8 "
f. " " neck, eye, and forearm.....	2 "

Forty specimens from hog No. 4:

a. Pillars of diaphragm.....	40 trichinæ.
b. Muscles ".....	30 "
c. " " larynx.....	10 "
d. " " ribs.....	10 "
e. " " tongue.....	6 "
f. " " forearm.....	2 "

According to Gerlach:*

One grain of flesh from the psoas muscles gave 161 trichinæ.

" " " diaphragm	" 129 "
" " " larynx	" 126 "
" " " tongue	" 105 "
" " " orbital muscles	" 64 "
" " " abdominal	" 54 "

† "Deutsche Klinik," July and August, 1872.

Not having any opportunity to make detailed examinations of the muscles of any whole or single hog, I could not obtain any personal observations of the percental dispersion of the trichinæ over the different muscle groups, or parts of any of the hogs I examined. Coming upon a piece of a pillar of the diaphragm which was wonderfully infected, I made the following numerical observation: 0.65 (5 centigrammes) contained at least 50 trichinæ; one gramme would therefore contain 1,000; four grammes, 4,000; a pound, 400,000; and, if we assume the muscles and flesh of a hog to weigh one hundred, its organism—were equal dispersion of the trichinæ possible—would lodge 40,000,000.

The immense multitude of these parasites which may be found infecting a single organism is still more wonderful than their wide dispersion over the same.

Leuckart estimates that, in some of the cases (human) which have come under his observation, a single gramme of flesh lodged from twelve to fifteen hundred, and, assuming the muscles of man to weigh forty pounds, the number of parasites infecting a human body, at such a ratio, would sum up thirty millions.

In Zenker's case (to be noticed later), Fielder calculated that the body of the woman must have lodged some ninety-four millions; and Cobbold assumes that *one hundred millions* of the capsulated parasites may sometimes infect one organism at the same time.

Leuckart again says "that no one who, like himself, had found some sixty trichinæ in ten mmgms. of muscle, would doubt the correctness of the preceding estimates."

In a report of the Chicago Academy of Sciences it was estimated that one cubic inch of pork, examined under their auspices, contained some ten thousand, and that a person consuming the ordinary amount of flesh taken at a single meal would introduce into his system more than one million trichinæ.

Rauch found numerous trichinæ infesting the muscles of a hog; of three hundred microscopic specimens, they were lacking in but three. In some specimens he observed thirty in one focus; in others, but five or six. As in seventy specimens, weighing one gramme, 350 trichinæ were discovered, one pound would lodge 175,000, and one hundred pounds 17,500,000. In many cases the parasites are much less frequently met with, and one has to search through many microscopic specimens before meeting with any, and then only with isolated examples.

When sufficient time has elapsed since the invasion of the muscles and formation of the capsules, the latter may be recognized, microscopically, as small, white specks; such muscles appear as if sprinkled with grains of white salt or sand. The calcification of the capsule begins about the fifth or sixth month subsequent to the invasion of the muscle.

It has been said by some observers that the trichinæ capsules in the hog do not calcify; others assert the contrary. The polariscope, however, reveals the presence of calcareous salts in the capsule, if sufficient time has elapsed since invasion. The reason why they may not be so easily seen as in human flesh must be sought in the influence

upon the salts exerted by the fatty oils of the porcine organism, which renders the crystals less visible.

INTESTINAL TRICHINÆ.

So long as the trichinæ remain encapsuled in the fibers of the muscles, their condition remains unchanged. They make no progress in their development, irrespective of the number of years that they may have been imprisoned. They have been seen in an active condition, i. e., capable of progressive development under favorable circumstances, for thirteen, twenty, and even twenty-four years from the time the invasion was known to have taken place.

a. In 1861 a woman was admitted into the public hospital at Altona, Germany, suffering from a mammary cancer which had been developing some twelve years. On its removal its tissues were subjected to microscopical examination, and trichinæ found infesting its fleshy parts. Upon inquiry, it was ascertained that, in 1856, the woman had resided at Davenport, Iowa, where she was taken suddenly ill, gastric and rheumatic phenomena being the most pregnant of any, together with œdema of various parts, and paralytic symptoms. Her brother, with whom she resided, was attacked in a similar but less severe manner at the same time.

The woman died at the above-mentioned hospital in 1864; an examination of her muscles revealed the presence of great numbers of encapsuled trichinæ. A cat fed with pieces from these muscles died in the course of sixteen days, its flesh being completely infested with the parasites.

b. Virchow reports a case where, after the lapse of twelve and a half years, the parasites moved in their capsules after prolonged exposure of the specimens on the microscope to the sun's rays.

c. Klopsch* mentions a case of trichinosis, with complete recovery, which took place in 1842. The parasites were discovered in the muscles of this individual twenty-four years afterward, on the excision of a mammary cancer.

d. Professor Damman, † of the Eldena Agricultural Academy, mentions a very interesting case, illustrating the longevity and tenacity of life possessed by muscle trichinæ, as infesting a hog.

This hog was fed with trichinous meat November, 1864, and in February, 1865, presented to the experiment station at Eldena. Since that time the animal had been kept isolated, unless when it was removed from its pen for examination. On February 3, 1875, and February 12, 1876, Damman removed a small piece of flesh from the muscles of the shoulder; at both times trichinæ were found. A considerable piece of flesh was removed and fed to two rabbits, and eighteen days subsequently their muscles were found to be plentifully invaded with trichinæ. This case demonstrates, beyond all question, the presence of living trichinæ, which were capable of maturing, fructifying, and developing young, when fed to other animals, after a period of eleven and a half years from the time that invasion of the hog took place.

Although the encapsuled trichinæ suffer no changes while confined in the muscles of an autotistic organism, yet the introduction of portions of such flesh into the intestinal canal of man, or other suitable autotite, causes rapid changes in their condition. The processes of digestion soon set the imprisoned parasites free from their cell-prisons, three to four hours being sufficient to this purpose; the freed parasites rapidly complete their development and become mature trichinæ, thirty to forty hours answering for this evolution; in cases of fresh invasion, when the capsules have not become dense, twenty-four hours have been sufficient to demonstrate the presence of sexually matured trichinæ in the intestines of animals fed with such flesh by way of experiment; nevertheless, we may often find trichinæ inclosed in their capsules on the third day after feeding infected flesh to an animal. There is scarcely another helminth by which this matured stage is reached in so short a period. Under these circumstances it is self-evident that the changes necessary to maturity must be of a very insignificant nature.

As a rule, sexual connection takes place within two days from the time the trichinæ become free in the intestines of an autotite.

The parasite increases in length and thickness, and with the female we may observe the uterus filled with fructified ova, which soon develop into embryos. The female intestinal or matured parasite lives from five to six weeks, and produces at least fifteen hundred embryos (Leuckart).

The newly born embryos are at first buried in the mucus which lines the intestinal canal; microscopic examination of the same, at this time, will reveal them as free and movable parasites. The embryos soon begin their migration and dispersion over the organism of their host, the first act being penetration of the intestinal parietes. It seems to be still a matter of discussion as to the means or ways by which further migration takes place. Some authors—in fact, all the most eminent—favor the view that the parasites proceed by way of the mesenterium and connective-tissue tracts over the organism, and penetrate the sarcolemma of the muscles.

Another view—the possibility of which, to a minor degree, is conceded by the advocates of the above-mentioned theory—is that the embryos gain access to the circulation, and are transported over the organism by the moving fluid, boring the smaller blood-vessels at convenience, and thus gaining access to the muscles (Thudichum).

Were this the principal path by which trichinæ become dispersed over an invaded organism, we should be able to discover numerous examples in the circulating fluid of living animals that have been subjected to feeding experiments. This is not the case. The following passage from the life of this parasite sufficiently emphasizes the fact that the ordinary process of migration is not the means by which the parasite gains access to the muscles for his own infection.

While the consumption of infected flesh is, in general, the means by which the disease takes place, this mode of transmission excludes the possibility of the infection of an animal taking place by intestinal trichinæ (embryos) which have passed from an already infected organism with its feces. In this

* Virchow's "Archiv.," vol. xxxv., p. 609.

† "Zeitschrift für pract. Thierheilkunde," 1876, vol. ix, p. 92.

way an infected swine may infect others, or, in fact, give occasion to a secondary invasion of itself, by rooting in the manure of its pen. *In the same way swine may become trichina-infected from human beings that have consumed trichinous pork, when, as is too often the case, the out-houses for the family are placed over the pig-pen, or lead into it, or when the contents of the same are thrown into the pig-pen for the swine to work over.*

Thus, we see the cycle of trichina-invasion may frequently continue from swine to man, and man to swine.

Trichinae may be assumed to be regular cosmopolitans. Whether Noah took a pair of them with him into the ark is probably an open question. They have been discovered in Germany, England, Scotland, Denmark, Sweden, Russia, France, Italy, North and South America, Africa, India, Austria, Spain, Egypt, and Syria. In fact, it may be said that they have been found infesting pork in whatever land and wherever they have been sought for.

As to their presence in any other animals than man and the hog, they have been found infesting the muscles of the cat, dog, rabbits, rats, mice, the marmot, the wild hog of Europe, and even the hippopotamus. Gerlach has produced invasion in calves and horses, but Leisering's experiments were unsuccessful in the latter. Several reports have been published with reference to the discovery of trichinae in the flesh of fish and other cold-blooded animals; but they all fail of experimental proof, and are nonconformable to our knowledge of the physiological activities of the parasite, which becomes torpid in a temperature a few degrees below that of the ordinary living mammal.

For some unknown reason they do not seem to be able to invade the flesh of fowls, though some authors claim to have found them in the intestines. A case of trichinosis among some soldiers from eating a goose is reported in the "Philadelphia Medical Times," April 13, 1878, the accuracy of which is very questionable, as pigs are fully as easily stolen as geese, and no evidence exists that a microscopic examination of the flesh of the goose was made.

With regard to the invasion of hens, the following experiments may not be without interest:

1. I fed them with highly infected pork in the natural way. Results: negative; no trichinae either in the flesh or intestines.

2. Assuming that the trituratory powers of the gizzard might be sufficient to destroy the parasites before they could gain access to the intestines, I caused a quantity of infected pork to be chopped for several hours until it became a veritable mush. Microscopic examination of the same revealed the presence of numerous *living* trichinae, when heat was also applied. This mass was stirred up with lukewarm water, so that it could be drawn into a coarse syringe; the intestines of several hens were then washed out by warm injections as cleanly as possible, and then several syringefuls of the mass were injected, and the outflow completely stopped by artificial means, which were removed after the lapse of forty-eight hours. Results: negative, though the hens were allowed to live for four weeks.

3. The abdominal cavity of six hens was opened, and two tablespoonfuls of the watery mass, but thicker than that

used for the injections, poured into them; the aperture was then sewed up. The hens drooped for a few days, but recovered, and ate well. Results: negative, though a queer-looking condition of the abdominal cavity was revealed. Why septicæmia did not set in is a mystery to me.

Lack of means, and want of support by the State Board of Health, prevented my carrying on many desirable experiments.

(To be concluded.)

TRANSFUSION IN GAS-POISONING.

By HENRY J. GARRIGUES, M. D.,

NEW YORK.

On the 17th of February last I was requested by Dr. Ferd. E. Valentine to assist him professionally in the treatment of a case of poisoning with illuminating gas.

A gentleman, forty-two years old, of excellent constitution and of strong build, on retiring in the evening, had blown the gas out, instead of turning it off. The room had the size of an ordinary hall room, and there was only one gas-bracket, placed near the window. The next morning, at six o'clock, a strong smell of gas was noticed in the corridor, and traced to the room occupied by the said gentleman. The door and transom being locked from within, an entrance was made through the window. The air in the room was suffocating; the stop-cock on the gas-fixture was found open; and in the bed the gentleman was found lying unconscious. Dr. Valentine and Dr. James H. Anderson applied hot bottles and mustard plasters to the skin, had the feet rubbed with a stiff brush, made him smell ammonia, and instituted artificial respiration. When I saw the patient, at 8 A. M., he was lying on his back; the face was pale, the conjunctivæ injected, the pupils dilated to the utmost degree and immovable. A well-marked strabismus internus was present. The breathing was puffing—22 per minute. The pulse was barely perceptible at the wrist—108 in the minute. Reflex action was active, but consciousness entirely gone. He frequently ground his teeth. Some subsultus of the tendons was observed, and all the muscles were in a high state of contraction, especially the flexors. The hands were clinched, the arms bent over the chest, and the knees drawn up.

I suggested to bleed the patient and perform transfusion, which being unanimously agreed upon, we proceeded at once to the operation. I took eight ounces of blood from the arm of a strong and healthy young negro. While it ran into a bowl, Dr. Valentine kept beating it with a fork. Next it was strained through a double layer of muslin—a clean pocket-handkerchief—in a tin funnel, and received into another bowl placed in a basin with hot water.

While the blood was being strained, I tightened a bandage above the elbow of the patient. No veins became sufficiently prominent at the elbow, but I could distinctly feel a branch of the basilic a little lower down on the forearm. I made an incision, three quarters of an inch long, through the skin, at an acute angle with the course of the vein, and dissected the adipose tissue off from the vessel. I introduced a probe under it, and bent it at the upper end,

so as to form a hook, preventing the probe from falling. I made a small incision in the vein with a lancet, and evacuated about eight ounces of dark blood. While the blood was flowing, the breathing improved somewhat. When Dr. Valentine reported that the pulse on the other arm became very small, we stopped. Then I introduced the nozzle of the transfusion apparatus, which I constructed and described in 1878 (see "American Journal of Obstetrics," vol. xi, p. 754), into the vein, which it filled entirely. Assisted by Dr. Anderson, I injected very slowly about six ounces of the defibrinated blood. During the injection, which took about three quarters of an hour, the pulse became fuller and sank to 92 per minute, and the breathing, although retaining its frequency, became so natural in character as to resemble that during normal sleep. When we had finished, the patient could be roused sufficiently from his comatose condition to make him swallow some ammoniated water and black coffee; but, as he was yet very sleepy, he was constantly roused by Dr. Valentine, by means of flagellation and the application of the electrodes of a Gaiffe's faradization apparatus, one of which ended in a metallic brush.

Three hours later he was sufficiently aroused to recognize his friends, and even speak a few words. The pupils had become smaller, and responded to light. At the end of the next two hours, consciousness had so entirely returned that Dr. Valentine, who at that time was the only physician present, allowed him to take short snatches of sleep. At half-past seven, pulse and respiration were normal; the patient laughed and chatted cheerfully, and had only a slight headache. As a precaution, he was ordered to be waked up every hour during the night. The next morning he felt perfectly well, except some soreness produced by the divers cutaneous stimulants used on the previous day. His pulse was full, and beat 64 in the minute.

The symptoms were those commonly observed in poisoning by oxide of carbon, with the exception of the color of the blood, which in that poisoning is said to be light-colored, like arterial blood. In our case it was dark, as venous blood commonly is. This is probably due to the fact that illuminating gas is carbon *hydrogen*.

I report this case in order to call attention once more to the advantages offered by transfusion. Here it was not a case of acute anemia which called for the operation, but one of toxæmia. We had to deal with a man who, although somewhat improved by cutaneous stimulation, was yet in a very precarious condition. The mere evacuation of some of the poisoned blood gave some relief, but the effect of the injection of fresh, defibrinated, healthy blood, full of oxygen, was instantaneous, and impressed all of us most favorably.

The operation itself is so simple that anybody who can use a knife and a forceps intelligently can perform it. With a single exception, the implements needed are so common that they are found in every house, or can be procured at the shortest notice. If a funnel is not at hand, the bottom may be knocked out of a wine-bottle, and the upper part used to sustain the cloth serving as strainer.

Only one particular instrument is required besides what

every physician carries, or ought to carry, in his pocket-case, namely, the transfusion apparatus. Most of these instruments are so bulky, fragile, and expensive, that the general practitioner rarely possesses one. It has been suggested that an aspirator might be used; but it is difficult, if not impossible, to keep this instrument so scrupulously clean and aseptic as a transfusion apparatus ought to be. And, like all piston instruments, it has the fault that, as a rule, it does not work when needed. In cities a fine catheter, a piece of rubber tubing, and a small funnel may, perhaps, be obtained in a drug-store; but this is by no means sure, and such a catheter will very likely be found quite difficult to introduce in the small, collapsed vein into which commonly the transfusion must be made.

My apparatus has the advantages of being small, light, and flexible, easy to keep clean, easy to introduce into a small branch of a vein, easy to manage even without skilled assistance, and quite inexpensive. It was originally made by George Tiemann & Co., 67 Chatham Street, who sell it for \$4.00. A chief point in the operation is to inject so slowly that the blood enters the vein merely in a thin stream, or almost drop by drop. After having been used, the apparatus must be taken to pieces, and every part of it scrubbed and disinfected by immersion in a five-per-cent. solution of carbolic acid. When it is to be used again, it suffices to let some clean water go through it before it is used for the blood. All air must be driven out by compressing the bulb entirely; but, when once the whole apparatus is filled with blood, it ought only to be worked by slight compression between the thumb and the index finger.

I am not aware that transfusion has been used before in cases of poisoning; but the striking effect obtained in our case ought to recommend it in similar occurrences.

A CASE OF PAINLESS LABOR IN A PATIENT WITH PARAPLEGIA.

By FRANK W. EPLEY, M.D.

NEW HAVEN, CONNECTICUT.

On the 12th day of April, 1877, I was called to see Mrs. W., a native of Ireland, mother of ten children, and about forty-three years of age.

In 1864 she had been a subject of hemiplegia, and helpless for several weeks. The attack, however, terminated in ultimate complete recovery, with the exception of a certain mental weakness noticeable to friends.

Upon my arrival, I found a somewhat spare woman, of medium height, moderately well nourished, and of nervous temperament. She was pregnant, had carried to term, and labor had begun at about 6 A. M. of that day. She had felt well, and had dressed herself that morning.

A neighboring physician had been called upon (as arrival, I found the patient had passed out all day quiet. Upon interrogating her, he found there had been no any vent to the lower extremities, and that she was suffering from a severe headache. Some after, the husband became satisfied that all was not right, and called me in. Upon my arrival, I found on the vulvar opening a flat tumor, dense and firm, occupying the

whole of the inferior portion of the recto-vaginal septum and interfering materially with the subsequent introduction of the forceps. There was no sign of fluctuation, either then or afterward. The os was soft, and opened to about the size of a silver dollar. There was complete paraplegia. I introduced a catheter and relieved the bladder of about two pints of thick, flocculent, ammoniacal urine, and ordered a copious enema, which brought away a large amount of fecal matter, without the least knowledge on the part of the patient that anything was being done, so far as sensations were concerned. I then left the case to nature, and ransacked my library for light upon the subject.

On the morning of April 13th I visited the patient again, accompanied by my friend, Dr. C. F. King. There had been no progress, so far as the labor was concerned, for twenty-four hours. Paraplegia was complete. The patient had not rested or taken food. The abdominal walls were flaccid, the uterus seemed in the same condition, and it was with a good deal of apprehension that we proceeded to effect delivery with the forceps. This was finally accomplished, without, so far as could be detected, the least action of the uterus. As traction was made with the forceps, the uterus and its contents were compressed firmly through the abdominal walls. We had expected hæmorrhage, and we had it, but not to the extent we had feared. After the removal of the placenta, the uterus was held firmly in the pelvic cavity until the hæmorrhage had nearly ceased, when a large compress and firm binder were substituted. The child was still-born.

During the manipulations with the instrument the patient felt no pain except rhythmical grinding pains in the epigastrium; after the delivery, the vaginal tumor was examined, but nothing more was discovered except that it appeared somewhat more enlarged.

The next day, April 14th, the temperature reached 103° Fahr., and on the 16th 104°. The patient had chills and all the symptoms of septicæmia, though the lochia were normal, except that the discharge was slight unless the patient's position was changed. The urine and feces passed without the knowledge of the patient. The vagina was kept cleansed by injections of a one-to-twenty solution of carbolic acid.

On the morning of April 20th, upon my arrival I was told that "that lump had broke and run awfully." The opening had taken place a little to the right of the median line and just within the vulva, and a probe readily followed a sinus leading up the recto-vaginal septum for a distance of about eight inches, then going to the right of the rectum, terminating in the region of the promontory of the sacrum. This was syringed several times daily with disinfectants, and in due time (about two months) healed. Her temperature became normal, or nearly so.

The paralysis continued, however. Bed sores formed on both hips, and finally over the sacrum. These were very deep and fetid, though perfectly painless.

The lower extremities became very œdematous. On the 22d of August, assisted by my friend and student, Dr. George Jackson, I removed the coccyx and a good share of the now carious sacrum. The patient failed gradually, and died on the 20th of September. No autopsy could be obtained.

Clinical Reports.

WOMAN'S HOSPITAL.

Reported by JAMES R. GOFFE, M. D., House Surgeon.

(SERVICE OF DR. THOMAS ADDIS EMMET.)

TWO CASES OF LACERATED CERVIX UTERI.

CASE I.—Mrs. Annie K., aged twenty-nine, birthplace Ireland, was admitted to the Hospital April 13, 1882. Has been married seven years, and is the mother of four children. Never had a miscarriage. Her first child was born six years ago; labor tedious, continuing for thirty-one hours (was attended by a midwife). Last labor, eighteen months ago. All confinements terminated naturally, i. e., no instruments were used. She has suffered since the birth of first child with "falling of the womb," which has grown worse with each succeeding labor. Has suffered with almost constant leucorrhœa, and during the past two years with imperfect control of bladder. The womb comes "out into the world" when on her feet for any length of time. She menstruated first at the age of fifteen, but only once. Then there was an entire cessation for two years, during which time she was perfectly well. Since the re-establishment of menstruation, the periods have occurred regularly.

On examination, there was found a rupture of the perinæum down to the sphincter ani, an extensive proctocele, and bilateral laceration of the cervix down to the vaginal junction, with so-called elongation of the anterior lip, that snout-like condition so frequently seen. Evidences of old cellulitis were also found in the left broad ligament, causing the uterus to be tilted somewhat to the left side. The patient was immediately put on hot-water treatment with astringent applications, and the uterus was held in place by a cotton-pad.

April 25th.—Dr. Emmet closed the cervix in the following manner: The lips were denuded on each side in the usual way, except that the angle of denudation was extended slightly forward and laterally into the vaginal mucous membrane in such a manner as to make the length of the denuded surface on the posterior lip as long as its corresponding surface on the anterior lip. Silver sutures were then passed, making the point of entrance of each successive suture in the anterior lip exactly the same distance from the angle as its point of exit in the posterior lip. The surfaces were thus accurately approximated, and the last suture on each side necessarily brought the tip of each lip in contact with the tip of the other. By this means, the apparent superabundant tissue of the anterior lip was disposed of and the cervix made symmetrical.

May 4th.—The stitches were removed, and union was found perfect.

May 24th.—Perinorrhaphy was done, the denuded surface being extended up the rectal wall to an unusual extent for the purpose of relieving the proctocele.

June 1st.—Stitches removed; union complete.

June 12th.—Discharged cured.

The interesting points in the case were the methods of denuding and approximating the lips of the cervix. Dr. Emmet thinks that the so-called elongated anterior lip so often seen is not due to actual increase of tissue in the cervix itself, but to a sort of preputial fold of the vaginal and bladder wall at their junction with the cervix. This he demonstrates by passing a sound into the bladder, and depressing the wall just anterior to the cervix. It is then seen that the distance from the vaginal junction to the extremity of the anterior lip is only normal.

CASE II.—Mrs. Sarah C., aged forty, Ireland, was admitted

to the hospital April 17, 1882, with the following history: Married seventeen years; children, four; miscarriages, five—all since birth of last child, ten years ago. First labor sixteen years ago, severe; ruptured the perineum. Last labor ten years ago. Commenced with flooding; child extracted with forceps. Menstruated at fourteen; regular; duration five and six days; normal in amount; no pain. For past two years has menstruated every two weeks; very profuse. At times has frequent and painful micturition, lasting several days; at other times does not pass water more than once in twenty-four hours. Bowels confined. Tires easily. Eight years ago had perineum closed.

Examination disclosed a bilateral laceration of the cervix down to the vaginal junction, with cystic degeneration of Nabothian glands in both lips, and apparent elongation of the anterior lip. She was put at once on the usual routine treatment—hot douches, puncture of the cysts, and iodine applications.

May 9th. Dr. Emmet closed the cervix, denuding the lips and approximating the surfaces as in the foregoing case. The angle of denudation extended out so far on the vaginal wall that, in passing the sutures, one passed through into Douglas's cul-de-sac. Dr. Emmet remarked that it would entitle the patient to some peritonitis, but the suture was not withdrawn, and the patient, however, had no unusual symptoms.

May 18th.—Left side perfect. Nearly all the stitches on the right side have cut out. These were removed, ether was administered, and the surfaces were again approximated by six sutures.

May 25th.—Sutures removed; edges inclined to roll out along the line on right side; ordered applications of nitrate of silver.

June 1st.—All irregularities smoothed down; cervix symmetrical.

June 8th.—Discharged cured.

The same demonstration of the preputial fold of vaginal and bladder wall was made as in the case above.

Book Notices.

A Dictionary of Medicine, including General Pathology, General Therapeutics, Hygiene, and the Diseases Prevalent to Women and Children. By various writers. Edited by RICHARD QUAIN, M. D., F. R. S., etc. New York: D. Appleton & Co., 1883. Pp. xviii-1,816.

It is seldom indeed that the editor of a variorum work meets with the good fortune to secure so large and efficient a corps of collaborators as are included in Dr. Quinn's list, which embraces the following well-known names: Mr. William Adams, Dr. William Aitken, Dr. T. Clifford Allbutt, Dr. W. H. Allchin, Dr. George W. Balfour, Dr. Robert Barnes, Dr. H. Charlton Bastian, Dr. C. G. H. Bäumler, Dr. Marcus Beek, Mr. Edward Bellamy, Dr. J. Henry Bennett, Sir J. Risdon Bennett, Dr. Carl Binz, Dr. J. Syer Bristowe, Dr. W. H. Broadbent, Dr. C. E. Brown-Séquard, Dr. T. Lander Brunton, Dr. George Buchanan, Mr. H. T. Butler, Dr. Thomas Buzzard, the late Mr. G. W. Callender, Dr. W. B. Carpenter, Mr. R. Brudenell Carter, the late Dr. J. Lockhart Clarke, Dr. W. Fairlie Clarke, the late Mr. J. T. Clover, Dr. T. Spencer Cobbold, Dr. Alexander Collie, the late Sir John Rose Cornack, Mr. T. B. Curling, Dr. J. Matthews Duncan, Mr. Arthur E. Durham, Dr. M. G. Echeverria, Dr. William Ewart, Dr. Robert Farquharson, Sir Joseph Fryer, Dr. Samuel Fewieck, Dr. David Ferrier, Dr. Balthazar W. Foster, Dr. E. Long Fox, the late Dr. Tilbury Fox, Captain Douglas Galton, the late Mr. George G. Gaseoyen, Dr. Samuel Gee, Dr. Rickman J. Good-

lee, Dr. Clement Godson, Dr. W. R. Gowers, Dr. T. Henry Green, Mr. J. Warrington Ilaward, Dr. G. Ernest Herman, Dr. J. Braxton Hicks, Dr. Berkeley Hill, Mr. Timothy Holmes, Dr. Benjamin Iloward, Mr. Jonathan Hutelinson, Sir William Jenner, Dr. Joseph Jones, Dr. P. W. Latham, the late Mr. Harry Leach, Dr. J. Wickham Legg, Dr. Robert Liveing, Sir William MacCormac, Mr. Charles Macnabara, Dr. John Macpherson, Dr. T. More Madden, Dr. Patrick Manson, the late Dr. Charles Murchison, Mr. Edward Nettleship, Miss Florence Nightingale, Dr. W. M. Ord, Sir James Paget, the late Dr. Edmund A. Parkes, Dr. F. V. Pavy, the late Dr. T. Bevil Peacock, Dr. W. S. Playfair, Dr. G. Vivian Poore, Dr. R. Douglas Powell, Mr. J. Netten Radcliffe, Dr. Frederick T. Roberts, Dr. William Roberts, Dr. Alfred Sangster, Dr. R. Saundby, the late Dr. Edward C. Seaton, Mr. John Simon, Dr. Alexander R. Simpson, Dr. Eustace Smith, Dr. Robert Sonthey, Dr. T. Grainger Stewart, Mr. J. F. Streetfield, Dr. George Thin, Sir Henry Thompson, Dr. J. C. Thoroughgood, Dr. J. Batty Tuke, Mr. T. Spencer Wells, Sir Erasmus Wilson, and Dr. Alfred Wiltshire. We have mentioned only the names of those of the contributors who are well known in this country.

The preparation of this great work must have occupied Dr. Quain and his collaborators for several years back, and they are all to be congratulated on having brought it to so satisfactory an issue. The book is in reality a cyclopædia of medicine and surgery, the special and very decided merits of which are, that it is not the product of one man's grubbing, of the sort exemplified in the past by the cognate works of Copland and Cooper; that it is not so diffuse and interminable as the great German work now in course of publication under Eulenbarg's supervision, or as the various French cyclopædies; but that it certainly presents, within a reasonable compass, such a picture of the medicine and surgery of the present day as will prove serviceable as a guide to its readers for several years to come, and remain for all time a book of reference that will prove of the greatest value to those who in future years may have to undertake the task of inquiring into the facts and doctrines that they will find to have led up to the period of their own work.

The volume is a handsome one. Although the type is small, the printing has been done so well that the page is not at all irksome to the eye. The fact that there is but one volume seems to us a decided advantage. Large type and the avoidance of bulkiness are highly desirable in the case of books intended to be read through in course, but, in the case of cyclopædias, multiplicity of volumes becomes far more objectionable than the large size of a single volume.

System of Surgery: Practical and Theoretical, and Operative. By SAMUEL D. GROSS, M. D., LL. D., D. C. L. Oxon., LL. D. Cantab., Emeritus Professor of Surgery in the Jefferson Medical College. Illustrated by upward of sixteen hundred engravings. Sixth edition, thoroughly revised and greatly improved. In two volumes. Philadelphia: Henry C. Lea's Son & Co., 1882. Pp. xxxii-35 to 1194, inclusive. \$10.00 net.

[illegible]

form, and the theories of the best English and German pathologists are stated clearly. Upon this subject Dr. Gross wisely remarks that it is not by following a theory, or theories, that we can become intimately acquainted with this subject, but by close and continued observation and reflection. We should expect that a man of such habits of thought would be conservative; hence it is that he adheres to his belief, in the value of bleeding as a therapeutic measure. In this view he is not alone. The same conservative turn of mind has prevented him, we think, from recognizing the great merit of antiseptic surgery, and of according to Mr. Lister that generous recognition of merit which his great services to humanity deserve. With clean, sweet hospitals, the older generation of surgeons are apt to forget the pre-antiseptic days when a surgeon opened a joint, or performed almost any of the major operations, with fear and trembling as to the result. The revolution does not consist in the use of carbolic acid, nor in greater technical skill, but in increased care and cleanliness. Dr. Gross has had opportunities to be useful such as few men enjoy. May he long be spared to humanity and to the profession.

The Principles and Practice of Surgery. By JOHN ASHURST, Jr., M. D., Professor of Clinical Surgery in the University of Pennsylvania, etc. Third edition, enlarged and thoroughly revised. With five hundred and fifty-five illustrations. Philadelphia: Henry C. Lea's Son & Co., 1882. Pp. xviii-33 to 1064, inclusive.

WITHOUT being so comprehensive a work as Gross's, Agnew's, or Holmes's, Dr. Ashurst's work furnishes an excellent manual for every-day use. It is essentially practical, and covers the wide field of surgery in as concise a manner as possible. The author offers no new theories for treatment or for operative procedure. In regard to venesection, he believes it is very rarely indicated, and has practiced it on very few occasions. Listerism he does not believe in, claiming that it is cumbersome, and leads to no better results than other methods. Certainly the results of Mr. Lister's teaching in Germany and France do not support the latter statement. The fact that the book has already reached its third edition is sufficient evidence of its acceptability to the profession.

A Guide to Therapeutics and Materia Medica. By ROBERT FARQUHARSON, M. D. Edin., F. R. C. P. Lond., late Lecturer on Materia Medica at St. Mary's Hospital Medical School, etc. Third American edition, revised by the author. Enlarged and adapted to the U. S. Pharmacopoeia by FRANK WOODBURY, M. D., Physician to the German Hospital, Philadelphia. Philadelphia: Henry C. Lea's Son & Co., 1882. Pp. 526.

DR. FARQUHARSON has tried, in this little volume, to put the great subject of therapeutics on a scientific basis. He has made no attempt at classification, yet his book is written from the stand-point of the physiological action of drugs. In his introduction he has given some admirable rules for prescribing. In the body of the work he has tried to follow what seems to us an excellent plan—namely, to present the physiological effects of the drug, and then to trace its therapeutical uses from these effects. The tendency to make practical application of physiological facts is growing among medical men. This third edition is heightened in value by the excellent additions made by the American editor. We do not hesitate to pronounce it the best book of its size on the subject in the English language. We wish it were more complete on many subjects, but for its size it goes over as much ground as it is possible to do.

Lectures on the Pathological Anatomy of the Nervous System. Diseases of the Spinal Cord. By J. M. CHARCOT, Professor to the Faculty of Medicine of Paris, etc. Translated from the reports by Dr. E. BRISAUD, in the "Progrès Médical," by CORNELIUS G. COMYGS, M. D., Lecturer on Clinical Medicine to the Cincinnati Hospital, etc. Cincinnati: Peter G. Thomson, 1881. Pp. xi-165. [Price, \$1.75.]

ANY book with the name of so noted an author as Charcot on the title-page will certainly be read with interest by the medical profession. The work under consideration fully supports the lecturer's reputation for original research and a thorough knowledge of his subject. The opening pages are devoted to a recapitulation of what is already fully understood concerning the topographical relations of the different segments of the cord, but as we advance we find that the chapters on the different varieties of degeneration, myelitis, localizations in the gray substance, etc., if not entirely new, present so many new features that the book can safely be recommended to both students and practitioners as a work of exceptional excellence. Numerous original illustrations help to elucidate the author's views.

As a translation, very little can be said in its favor. It contains several errors, and a great deal of badly expressed English. In the preface the writer informs us that his translation formed Professor Charcot's course for 1879-'80. Why Charcot should have preferred a poor English translation of his lectures to his native tongue is a problem which only the author of the foregoing remarkable statement can solve. Further on the translation is twice referred to as *they*. Taking these faults, and many others, into consideration, we are forced to agree with the writer when he says he is sure that others might have made the translation better than himself.

A Supplementary Catalogue of the Pathological Museum of St. George's Hospital: a Description of the Specimens added during the Years 1866-1881. By ISAMBARD OWEN, M. D., Curator. London: J. & A. Churchill, 1882. Pp. xxxiv-284.

THE pathological preparations described in this volume comprise those numbered from 3,403 to 4,284. The first volume was issued in 1866. References are given to the transactions of various societies, to the registrars' records of medical and surgical cases preserved in the hospital, so that one can readily find a full report of the case from which any specimen was obtained. If more of the hospitals would publish catalogues of the specimens contained in the different museums connected with them, much exceedingly valuable material would become available. The volume is well printed, and reflects much credit on the curator.

MEDICAL SOCIETIES AND PUBLIC WORKS.

It is getting to be quite a common thing for medical societies to be asked to pass resolutions, and perhaps utter a petition to the general Government, in favor of this, that, or the other scheme of public sanitation or some undertaking of one sort or another by which, it is generally asserted, the public welfare, as well as that of the profession, is likely to be conspicuously enhanced. This particular form of jobbery is most apt to crop out at meetings of the national or State societies, since most of those societies are convened but once a year, and have therefore little time to inquire into the real merits of the enterprises in furtherance of which their action is asked. Moreover, these societies have more ambitious names than those that do the actual work of the profession, and, professing to represent medical opinion as it prevails in the large districts from which they draw their membership, they naturally seem more available for the task of impressing the legislative mind.

We have no intention of implying that society aid is not often sought and obtained in favor of measures that are proposed with the utmost purity of intention, and that bear the unquestionable features of having been devised solely for the public good. We are persuaded, however, that in too many instances the advantage of the proponents is the real objective, a yearning for emolument, or official dignity, or the power of dispensing patronage being but scantily draped with the garments of the reformer. Trivial as the disguise is, it is very apt to enable the trickster to withstand any feeble objection that may come from the few who really see through it—partly because a certain number of votes may always be counted upon as the sincere tribute of the unsophisticated to supposed merit, partly because the great majority are apt to think that, if no good comes from the measure, at least no particular harm is likely to result, but chiefly from the unwillingness of a few men of discernment to undertake the ungracious task of making what would very likely be taken, they are apt to think, as factious opposition.

Much of the proceedings of these large societies, however representative they may profess to be, is not strictly deliberative, but rather of the frothy character indicative of its having been brought about by emotional agitation if not by intrigue. A little reflection would generally suffice to teach those who are hasty led into such action that it is not, on the whole, calculated to promote the public good. And so the aggressive "reformer" and *soi-disant* philanthropist carries his point, and, fortified by the express approval of an organized body supposed to be made up of the flower of his profession, takes his axe to Congress or to the State legislature to be ground.

No doubt the hollowness of such indorsements is seen

through by the great majority of our legislators, but let us not on that account be too ready to catch at the consoling reflection that the evil will work its own cure—it is so working its cure, to be sure, but there are certain collateral effects that are by no means desirable. Chief among these is the contempt with which such action on the part of our medical societies is coming to be looked upon by members of the law-making bodies, and the consequent increasing powerlessness of the medical profession to exercise any public influence in its organized capacity, even as the result of careful deliberation and a firm conviction. This is the position into which we are rapidly drifting, and one from which we can not rescue ourselves at once, but only by declining persistently and on all occasions to pass hasty resolutions in favor of any scheme whatever. Even unobjectionable projects should not be so bolstered up for some time to come, until we have regained the status we once enjoyed in the eyes of the community at large. Any matter of public policy that is really a fit subject for legislators to take advice upon from our profession can for the present best be furthered through the medium of our journals or by the efforts of individual physicians who are known to be men of systematic habits of thought and observation, mature training, broad tolerance, and utter freedom from the warping effects of personal influence.

ANATOMICAL STUDY.

EXCEPT those who are engaged in teaching anatomy, there seem to be few who pay any particular attention to the matter after having taken the degree of doctor in medicine. We refer now to ordinary gross anatomy, for we are well aware that many of the most industrious and most capable of those who are contributing to the advancement of medical science devote much of their time to questions of minute anatomy, which questions, it can not be denied, are of the highest importance in their bearing on physiology, on pathology, and indeed on various branches of experimental medicine. So, too, there are those among the surgeons who study regional anatomy on occasions, but their study has chief reference, we imagine, to some particular operative work that happens to be in hand at the time; hence, the surgeons seldom so systematize their labor in this field, or carry it to a stage beyond that in which it serves their immediate purpose, that any impression is made upon the notions held in general with regard to gross anatomy.

There are some notable exceptions to this statement, and it seems to us that those exceptions show such practical advantages gained that it may be well to mention a few of them. Restricting our survey to recent work by New York men, we would first specify the long-continued and admirable investigations, by Dr. Otis, of the normal caliber of the male urethra. Opinion, of course, is not yet settled as to how far Dr. Otis's practical deductions are to be accepted as applied to operative procedures designed to correct what he considers abnormalities, but what some others may look upon as not constituting noteworthy deviations from the normal state of things; but this want of accord in interpreting his facts does not take away in the slightest from the recognition due him of the ingenuity of

his investigations, or of the results that have grown out of their bearing upon matters of practice. It is not alone that the treatment of stricture hinges upon just such points as Dr. Otis's inquiries embraced; there can be little doubt that his demonstration of the normal capacity of the urethra paved the way to the great advances that have been made of late years in the treatment of vesical calculi, especially the operation of litholapaxy.

Another noteworthy example of the practical importance that attaches to anatomical researches is to be found in the manifest bearing of Dr. Thomas's study of the female perineum on the whole range of procedures having for their aim the mechanical restoration of the parts within the pelvis to their normal relations to each other. In this case, as in the former, we need not coincide with the investigator's views in order to reap benefit from his work; the main point is, to have the matter brought forward in proper shape, as has been done both by Dr. Otis and by Dr. Thomas, so as at least to awaken general interest in it, and lead others to go over the work for themselves.

TRICHINIASIS.

It is to be feared that the reproach will attach but too justly to the American people of having allowed commercial ambition, associated with a natural resentment of the unfair suspicions that have so often been cast upon them abroad, to shield those who have the hog industry in charge from too close an inspection of its products. As a matter of course, we have to contend with the rivalry of foreign purveyors of food-products—men who would show a most uncommercial mobility if they did not turn every circumstance and suggestion to advantage that could aid them in stemming the tide of importation from America. Allowing this consideration its full weight, still, the world has got past that period of its history in which the allegation of an animus was a good defense against an injurious charge.

It will not do for us to cry out that the envious pork-dealers of various European countries have but made the most of a popular dread in order to curtail American competition, and so protect themselves. The plea may be founded in truth, and doubtless is, but we must go further, and take the most stringent measures to guard against any confirmation of their statements. We must do our best to secure the absolute impossibility of trichinous pork being furnished by our dealers, either for home consumption or for foreign markets. In the language of Mr. Billings, whose initial article on the subject will be found in this number of the journal, we must "take some other course than evasion with reference to the contagious, infectious, and invasive diseases of our domestic animals."

Moreover, it will not do to content ourselves with adjuring people to cook their pork thoroughly. Cooked trichinae do not commend themselves to the discriminating, and they can not be called over-nice if they return curses for our advice. But there is one contention that, it seems to us, we are fully warranted in urging, viz.: that, while we will take all possible

measures to prevent the exportation of infested pork, and its exposure for sale at home, and while we do not deny that, when sent abroad, our pork may rightfully be subjected to the closest scrutiny, we do take the position that such scrutiny is all the bar that can with justice to us and to the European consumer be put upon the trade.

Although the past few years have witnessed a growing devotion on the part of our veterinarians to the strictly scientific aspects of their pursuit, as evidenced by the establishment of collegiate institutions for training, and the support of our early history, and as shown by the contributions to the literature of comparative medicine that are coming more and more often from our own veterinary practitioners, and showing a steady increase in value; still, veterinary medicine in America is not yet accorded by the general public the true dignity that its importance calls for, and that is the necessary prerequisite of its study and practice being undertaken to any great extent by a class of men who, as things stand, can more easily attain to eminence and prosperity in other pursuits. The period has not yet gone by when an advocate meets, not with rebuke, but with applause, in a dustardly attempt to break a man down on the witness-stand by hurling at him the epithet of "horse-doctor." All the more honor, then, should we accord to the few brave and devoted men who are able to stand up against this state of things.

CRUELTY IN LUNATIC ASYLUMS.

A short time ago, at the meeting of the National Association for the Protection of the Insane, held in Philadelphia, a paper was read by the Rev. Heber Newton, which commented severely on the manner in which the insane were treated in lunatic asylums. The paper made no local allusions, but a representative member of the profession in Philadelphia, and a neurologist of ability and prominence, is said to have denounced the essay in no measured terms, and to have made the rather gratuitous assertion that the insane were always well treated in Pennsylvania.

Passing over the barbarities which about two years ago were stated to exist in the lunatic department of the Bloekley Almshouse, and were so severely commented upon by Dr. Bucknill, we beg leave to call attention to some recent allegations in regard to the asylum at Dixmont, near Pittsburg. It is stated that "Dr. Julius Sevin, at one time a leading physician in Erie, became insane about eight years ago, and was sent to this asylum. He states that his reason was restored in less than two years after his incarceration, but that he was forcibly detained during the rest of the time. His letters to his friends were intercepted, and he was subjected to the most cruel indignities. At last, through the pity of a keeper, his letters reached his friends and he was released. Dr. Sevin brings charges against the managers of the asylum of inattention to the real condition of patients, and of detaining them for years after they are cured. Over sixty sane patients, he alleges, are now in the asylum. The keepers in some cases have been treated in the

treatment of the helpless patients. The superintendent, Dr. Reed, is presumably ignorant of these cruelties and neglect, as he leaves the actual care of the patients to young physicians and to keepers."

Now, as the "Tribune" remarks, these charges may or may not be true. They were made public, however, at almost the very time that the association alluded to was in session. A good deal of allowance must always be made, we grant, in accepting the statements of those concerning whose sanity there is any reasonable doubt, and we believe that in the greater number of instances in which complaints are made against asylum officers, either by former inmates or by officious "philanthropists," there will be found to be but the slenderest foundation, if any at all, for such complaints. However, occasional barbarities undoubtedly do occur, and will continue to occur so long as the superintendent's time is more given up to the care of property than to the care of patients. The point we would emphasize is, that it is better to investigate such charges than to deny them in general terms.

THE PENNSYLVANIA LUNACY LAWS.

THE public attention which has been drawn in this State to the defective legislation on behalf of the insane is bearing fruit in like attempts to improve the laws in neighboring States. An illustration of this may be found in General Butler's recent inaugural address as Governor of Massachusetts, a considerable portion of which was taken up with a summary denunciation of the management of all the public institutions for the care of the insane. It is the opinion of many that the facts did not fully warrant the statements made by the Governor, but it is certain that if there were faults of management, they will now be noticed and corrected. In Pennsylvania a commission was appointed not long since, by Governor Hoyt, for the purpose of examining the lunacy laws of Pennsylvania and reporting to the Legislature any recommendations in regard to them. This commission consisted of ex-Governor Hoyt, George L. Harrison, Dr. S. Weir Mitchell, Dr. Reed, and Richard C. McMurtrie, and well represented the legal and medical professions of Pennsylvania.

The commission has recently made its report, and its recommendations are more subversive of the existing law than those made for this State by the committee of the Medico-Legal Society of this city, a summary of which was recently given in this journal, for the reason that the laws of New York are more satisfactory than those of Pennsylvania on the subject.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

(Concluded from page 219.)

INTESTINAL OBSTRUCTION.—Dr. WEIR presented a specimen which illustrated intestinal obstruction occurring in the splenic flexure of the colon. The cause of the constriction was cancer. It was removed from the body of a woman thirty-three years of age, married, who entered the New York Hospital, November 28, 1882, in the medical service. She had had complete obstruction for nine days previously, associated during the last

few days with stercoraceous vomiting. The history was that she had had, some time last spring, an attack of intestinal obstruction, but not very severe, and from that time had suffered from attacks of constipation. The cause of the last obstruction could not be readily elicited, nor was any light thrown upon the subject by examination of the distended abdomen. It was recognized that there was great distension of certain coils of intestine, apparently in the site of the colon, though this could not be positively made out. Examination with the rectal tube showed that the gut could be penetrated to the depth of twenty-eight inches. This was accomplished several times, when large enemata were administered. These latter also established the fact that about one hundred ounces of water could be received the last time into the bowel without unduly distressing the patient when placed in the knee-elbow position. Prior to her admission to the hospital, which was on a Tuesday, she had received a great deal of treatment, the exact nature of which could not be determined. At the invitation of the Visiting Physician, Dr. Draper, Dr. Weir saw the case on Wednesday afternoon, at which time the patient had a temperature of 102° Fahr., pulse 120. These symptoms, together with the stercoraceous vomiting, the duration of the case, and the history of constipation of marked severity, led him to the conclusion that delay should not be continued much longer, and he therefore proposed a preliminary rectal examination. It was determined, however, to repeat the injections, and to wait until the following morning, and, if no relief was obtained, to then resort to surgical interference. Relief was obtained, the injections bringing away a certain amount of fecal material, and the discharge was followed by two additional fecal evacuations of a creamy, muddy color and consistence. The vomiting ceased, and the general condition of the patient was so much improved as to encourage postponement of the proposed surgical interference. On Friday the symptoms of obstruction again appeared, except the vomiting, the abdomen became more distended than it formerly had been, the temperature rose higher, and there was nausea and cessation of fecal discharge and flatus. On Saturday, Dr. Weir again saw the patient, and it was then learned that her general condition had very much depreciated within the last two days. Dr. Weir then proposed that the rectal examination be made, which was assented to, and he then introduced his hand (¾ in. in circumference) slowly into the bowel, but was unable to carry it up beyond the upper rectal pouch, though he could carry one finger sufficiently far to enable him to sweep over the caecal region. This, however, could not be recognized. He had proposed to perform a right lumbar colotomy if it had been determined by rectal exploration that the cæcum was distended, or, if unable to determine this point, to perform enterotomy. The patient, however, was so much prostrated by the ether and the examination as to forbid a resort to further surgical procedure. She did not rally, as was hoped, but gradually sank, and died twenty-four hours afterward. The autopsy revealed cancerous disease at the splenic flexure of the colon, so slightly perceptible externally as scarcely to be recognized. There was also a most minute secondary involvement of the liver. No injury had been done to the rectum by the manual exploration. The point of obstruction was twenty-three inches from the anus. The cæcum was apparently in the normal position, and not distended with fluid, but with air. To this point Dr. Weir wished to direct the attention of surgeons, because he had heretofore felt considerable confidence that, in cases of obscure intestinal obstruction, rectal exploration might be available as a means of diagnosis, and, by the recognition of a distended cæcum, might enable the surgeon to act with greater accuracy. In this instance such exploration had failed. The experience of Dr. Halsted, also, who would follow him in the presentation of a specimen, had led to

the conclusion that when the cæcum was distended with air it might not always be readily recognized by the touch. Another point to which he would like to ask attention was the diagnostic value of injections of water and of the rectal tube. Heretofore he had placed much reliance upon the rectal tube, especially when the French black tube was used, because this latter more readily showed on withdrawal any twisting or sharp bending that might have taken place. In two instances he had proved by operation, or by autopsy, that the site of obstructions had been quite accurately determined in this manner. He had found some difficulty in carrying the tube beyond the sigmoid flexure in the cadaver in four recent trials by Dr. Peabody; but in the living subject it could be introduced quite easily. This difficulty could be easily understood because of the difference in the condition of the parts. During life the intestines yielded to pressure more readily than in the rigid cadaver, and perhaps the end of the tube itself produced spasmodic contraction, and the gut consequently changed its position, or that of the end of the tube. As to the injection of fluids, there was an appreciable fallacy in that means of diagnosis, because the opening in the large intestine might admit the passage of fluid beyond it. That error was committed in one instance where there was a narrowing of the transverse colon, in which case he had performed right lumbar colotomy. Prior to the operation, large quantities could be injected, and but little return. In one trial of a large turpentine enema, the matter vomited was strongly impregnated with the odor of the injection, showing that the ileo-cæcal valve had been forced.

A final word might be added which would bear also on the case to be subsequently narrated. It was, that the pathologist of the hospital had, in remarking on the difficulty that would have been encountered in recognizing the site of the obstruction by a laparotomy, said that in six autopsies of intestinal obstruction he had lately made, he believed that in nearly every one from a similar cause relief would not have resulted from an operation.

INTESTINAL OBSTRUCTION.—Dr. W. S. HALSTED presented a specimen with the following history: ANNA B., aged thirty-five, Irish, widow, well nourished, mother of eight children (youngest five years old), was admitted to Charity Hospital, December 16, 1882, complaining of constipation, colicky pains, distension of abdomen, and vomiting. Patient stated that she had since her infancy been subject to similar, but less severe, attacks, and remembered five previous ones distinctly, the last having occurred in March of this year. Heretofore had been promptly relieved by "medicine," her symptoms having persisted on only one occasion for as long a time as two days, and their subsidence being always coincident with the escape of much flatus. Constipation had attracted the patient's attention for several days prior to the present seizure, which developed suddenly, about one week before admission, while she was drinking a cup of tea. Since then nothing had passed from the bowels. She vomited on the 15th for the first time a little mucus, and had continued to eject, at intervals of several hours, frothy mucus, and possibly bile, but at no time stercoraceous matters. House Physician gave a cathartic soon after admission. Dr. Halsted's attention was called to the case on the following day, December 17th. The recorded history being incomplete, he recited it as accurately as possible from memory.

Found the patient tossing from side to side, moaning loudly, and apparently in great distress; countenance slightly flushed, but not anxious. Respiration 27, pulse 98, temperature 98.5°. Thighs flexed, abdomen much distended, and unevenly so, everywhere tympanitic, and in no one region especially sensitive to pressure.

Diagnosis, intestinal obstruction. Prescribed morphia hypo-

dermically, and directed that enemata, as large as possible, should be administered with the longest available tubes.

December 18th.—Patient confident that she is convalescing. Assures us that she is free from pain, and has passed "wind" per anum. Respiration 22, pulse 104, temperature 98.5°. Can not ascertain positively how much urine has been voided, but nurse guesses four ounces in 12 hours. House Physician states that a hard esophageal tube was introduced last evening to its full extent (about twenty inches), and that only one quart of fluid could be injected, which, when evacuated, brought with it mucus, but no gas, and not a trace of feces. Repeated the injection myself with like result, and noticed that the tube was in several places most singularly bent and twisted.

December 19th, 1 P. M.—Patient very comfortable. Patient anesthetized. Assisted by Dr. Weir, proceeded to operate under carbolic-acid spray (1-40). Incision in median line from umbilicus to pubes. The peritonæum being divided, a small quantity of serous fluid escaped through the wound. The large intestine very much distended, and, presenting a few small, superficial ecchymoses, occupied the entire field of view, being folded upon itself longitudinally. The separation of the folds exposed the quite normal small intestine. After a somewhat prolonged and unsatisfactory search for the cause of the obstruction, which was evidently below the flexura ilioalis, there could be felt with the right hand a dense cylindrical band about the size of one's little finger, very deeply situated, and stretching from near the promontory of the sacrum obliquely upward and outward to the parietes of the left hypochondrium, not far from the tip of the twelfth rib. The abdominal incision was then extended to within about two inches of the xiphoid cartilage. The obstructing cord being exposed, it could be seen to have its apparent origin from the transverse colon, and was divided between two stout catgut ligatures, which were passed around it by means of an aneurism needle. Below the band, and clearly compressed by it, were two tubes of large intestine, one of which filled with air as soon as released, while the other did not. The patient's condition was too bad to justify much further investigation, although it was evident that the disposition of the sigmoid flexure was most puzzling, and possibly offered another obstacle to the escape of intestinal contents. The distended colon, which had been protected throughout the operation by towels warmed in a solution of carbolic oil (1-40), was replaced without very much difficulty, and the wound united by a double row of sutures; the deep, of silver, included the peritonæum.

December 20th, 1 P. M.—Patient has just died. Ever since the operation, was observed by internes and nurses to have passed large quantities of gas from the bowels.

December 21st, 1 P. M.—J. M. Halsted, M.D., presented a specimen of incision. Transverse colon slightly adherent to wound a little below umbilicus. Large intestine reached to fourth intercostal space on left side, and was found to be adherent to Fig. 5. Attached to the anterior surface of transverse colon at

about its middle, and having its origin in the great omentum, was one portion of the divided band with its catgut ligature, the other part being intimately blended, and apparently con-

FIG. 4.—Immediately after the Operation.

tinuous, with the diaphragmatic peritonæum between the eleventh and twelfth ribs. The specimens before you show the attachments of the band. Figs. 3 and 4, drawn in the light of the autopsy, are intended to illustrate what presumably existed before and immediately after the operation. The x's designate sigmoid flexure looped and twisted upon itself from right to left. The sigmoideo-rectal junction was sufficiently narrowed in the bight of the volvulus to prevent the ready escape of flatus per rectum. This constriction was evidently one of very long standing, and intensified somewhat by the underlying falciform fold of its mesocolon, which normally extends from the mesentery to the upper end of the rectum, and which, in this case, was unusually strong and prominent, with its concavity directed ventrally.

FIG. 5.—At the Autopsy.

The pathogenesis may, then, have been: First, non-inflammatory adhesion, in intra- or early extra-uterine life, of a considerable portion of large omentum (mesogastrium) to parietal peritonæum, adhesions of this nature being incidental to development, as urged by Larger and verified by Toldt. Second, embarrassed growth of sigmoid flexure, giving rise to a rotation of same which was permitted by the great length of the free mesocolon at that early period, or by its coincident development. Third, narrowed sigmoideo-rectal junction, its growth having been somewhat restrained, or its lumen reduced by pressure from without. Fourth, acute symptoms due, as suggested by Busch, to sudden distension of gut above and retraction of mucous membrane from below omental band, possibly preceded by further intrusion of descending colon under the site of constriction. I would suggest in similar cases the advisability of operating early, not only that the patient may survive the shock, but to anticipate a degree of hyperdistension of the intestine from which it can never recover.

If there is reason to suspect the existence of a further source of obstruction, or if the tension within the distended gut can not be decidedly relieved by simpler measures, I believe laparocolostomy or enterostomy, as the conditions may dictate, is indicated.

Dr. SANDS remarked that in Dr. Weir's case the failure to recognize distension of the cæcum was probably due to the existence of a band at the upper part of the rectum which prevented the hand of the operator from making the usual excursion. In one case he had been able easily to ascertain, by manual exploration of the rectum, a distended state of the cæcum, the patient having a stricture situated in the sigmoid flexure.

Dr. WEIR remarked that he had heretofore regarded manual exploration of the rectum as a reliable means of determining whether or not the cæcum was distended.

Dr. SANDS further remarked that in inserting the tube with the view of determining the presence of a stricture, it should be remembered that the constriction might be sufficiently close to cause abdominal obstruction, and yet not be so narrow as to prevent the passage of the tube. This condition was exemplified in a case he had already narrated to the society, in which the ordinary black French tube was passed a distance of eighteen inches without encountering any obstruction. When the patient died, a cancerous stricture of the rectum was found between six and seven inches from the anus, just large enough to allow the passage of the tube. Dr. SANDS said that Simon had shown conclusively that it was impossible to pass an elastic tube beyond the splenic flexure of the colon, and that, in cases where a great length of tube had been introduced, the end of the tube had been arrested at the splenic flexure, the mesocolon allowing the tube to curve toward the right side.

Dr. WEIR asked Dr. SANDS concerning the value of exploration by means of the tube in any portion of the large intestine below the splenic flexure. He himself had already attached considerable value to such exploration if properly and repeatedly performed.

Dr. SANDS regarded such exploration as very valuable.

Dr. A. G. GEESTER had observed a case somewhat similar to the one related by Dr. Halsted. In his case, however, he was able to detect at the operation the site of the obstruction. The patient was a boy thirteen years of age, who had suffered from peritonitis eight weeks previous to his last sickness. The peritonitis had subsided under the ordinary plan of treatment, and the patient had recovered to such an extent as to be able to go to school. Two weeks afterward he was attacked by something which appeared like peritonitis. Morphine was administered, and he seemed to improve under the treatment so far as to permit the physician to attempt to evacuate the bowels by means of an enema. From the moment the enema was administered, very violent and alarming symptoms of intestinal obstruction developed. The chief reason why the effort was made to evacuate the bowels was the complaint of fullness of the abdomen and entire absence of pain upon pressure. The symptoms which developed after the administration of the enema were intense vomiting and depression of the general system, with severe pain. The attending physician proposed to administer quicksilver to overcome the intestinal obstruction. A second physician was called, who found marked depression of the general system, feeble pulse, continued vomiting, and clammy perspiration, despite the narcosis which had been produced by morphine. Marked tympanites also existed. The child, when aroused from his semi-comatose condition, always pointed to the left side of the belly as the seat of the pain. Dr. Gerster saw the patient in consultation, and proceeded to surgical interference for his relief. He made an incision which extended from the umbilicus almost to the symphysis pubis. Immediately upon opening the abdominal cavity, the distended bowels rushed out through the incision and filled it so full that it was impossible to form any adequate idea with reference to the position or condition of the abdominal contents. He extended the incision sufficiently far to admit of a full view of the

abdominal contents, and then introduced his hand and felt most of the intestines to be movable, except one bunch, consisting of four or five loops, which were anchored in the right iliac fossa. Separating the loops of intestine constituting this bunch, he found they were bound down by a band one fourth of an inch in width, which passed across one loop of the mass and formed the true cause of obstruction. Upon closer examination, it was also ascertained that this apparent band was the vermiform appendix which had become evidently attached to the abdominal wall during the previous attack of peritonitis. It had passed across a portion of the ileum about five inches from the cecum, and its apex had become attached to the mesentery of the ileum upon the other side. The upper portion of the ileum and small intestine were intensely distended and hyperæmic, and the lower portion was pale and normal, as was also the large intestine. There was no evidence of acute peritonitis at the time of the operation. He applied a stout double catgut ligature to the band or vermiform appendix, and divided it between the ligature, whereupon the intestinal contents immediately rushed from the superior to the inferior portion of the ileum. Dr. Gerster then experienced great difficulty in attempting to replace the intestines within the abdominal cavity. Hoping to diminish their distended condition, he introduced the smallest sized hypodermic needle, but the escape of gas was so slow that he withdrew the needle, intending to perform a large number of punctures; but when the needle was withdrawn he noticed that one minute drop of intestinal contents followed, and appeared upon the external surface of the gut. He wiped the surface of the gut very carefully, and then introduced an elastic catheter into the bowel through the anus and administered an enema, his idea being that, the obstruction being removed, probably a portion of the intestinal contents could be removed in that way. The plan proved to be perfectly successful; the injection of hot water through the catheter brought away feces, and a large quantity of gas also escaped, followed by solid fecal masses. After the evacuation had occurred the intestines collapsed so much that no serious difficulty was experienced in restoring them to the abdominal cavity, and the wound was closed. The abdominal cavity was not exposed longer than twenty-five minutes, but the patient died of collapse about eleven hours after the operation.

Dr. HALSTED remarked that he also introduced a fine hypodermic needle into the distended intestines in his case, and observed precisely the same thing which Dr. Gerster had mentioned—namely, the exit of a small drop of intestinal fluid upon the withdrawal of the needle. Only a small amount of gas escaped, and that very slowly. Furthermore, Dr. Weir had retained the intestines in position to a considerable extent by means of towels which had been dipped in warm carbolyzed water, and after some manipulation they were returned to the abdominal cavity.

ENCYSTED NEEDLE IN THE LEG.—Dr. Post presented a portion of a large needle inclosed in a cyst which he had removed from a woman's leg about a hand's breadth above the internal malleolus. The patient was forty-five years of age, and gave the history that the portion of needle had been in this position during the last twenty-five years. The point of special interest in the specimen was that the needle was firmly encysted, the cyst as exhibited in the specimen almost completely surrounding it. At first it caused but slight irritation, and subsequently gave the patient no trouble whatever until a short time before she applied to him for relief. The needle was a large one, and the portion removed was two centimetres in length.

AFTER evaporating an aqueous solution of a stric juice prepared from the stomach of a sheep, Mr. J. Chaptout obtained a pepsin capable of dissolving 2,000 times its weight of fibrin. — *Times*.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

A REGULAR meeting was held December 14, 1892. Dr. JAMES TYSON, President, in the chair.

MITRAL OBSTRUCTION WITH SEVERE MITRAL LESION.—EXHIBITED by Dr. E. P. BRUCE. I submit this specimen because it favorably illustrates the lesion and the sequential changes in the different chambers of the heart. The auriculo-ventricular opening of the left heart is nearly occluded by an epiglottis-shaped enlargement of one of the leaflets of the mitral valve. The valve is very much thickened, and the focus of a considerable calcareous deposit. The orifice during life permitted a reflux of blood from the ventricle into the auricle. The left auricle is dilated and hypertrophied, so that its cavity is about twice as large as normal. The right ventricle is very much dilated. The walls of this cavity are less than half the normal thickness, and the ventricle must have had during life twice its physiological capacity. The tricuspid valves were insufficient on account of the dilatation. The considerable enlargement of the left auricle and right ventricle occasioned during life a broadening of the area of dullness on the level of the third and fourth ribs—viz., the apex of the cardiac triangle. It also produced a decided increase in the area of the cardiac dullness to the right of the median line of the sternum. In children, the heart, with similar enlargement, encroaches upon the left pleural cavity to such an extent that the physiological inflation of the left lung can not occur. Bronchial breathing is produced, audible posteriorly, while anteriorly below the second interspace no respiratory murmur is audible. In these cases, when the complication of bronchitis occurs, the physical signs suggest a pleural effusion. Enlargement of the right ventricle, both in children and adults, causes a pronounced impulse at the epigastrium, and occasions serious pain and inconvenience. The murmur heard during life in the case from which my specimen was taken indicated this lesion, both presystolic and systolic murmurs being audible. The second sound at the pulmonary artery cartilage was also much accentuated, owing to the repletion of that vessel with blood. The first sound over the right ventricle was very clear and distinct, as is common in these cases, but the first sound at the apex was obscured by the murmur. The patient from whose body these specimens were removed was a woman aged forty-six years, who had been subject to heart disease since twenty. The immediate cause of death was pulmonary repletion with blood, which induced right heart failure. Compared with cases of mitral regurgitation, this mode of death illustrates a feature of the clinical pathology of mitral obstruction. In mitral regurgitation death occurs with heart failure, but usually after serious dropsy. In mitral obstruction dropsy is not so prominent a symptom; but the pulmonary engorgement prevents a perfect supply of blood to the aorta. The right-ventricle failure in cases of mitral obstruction brings about death in the same manner as left-ventricle failure does in cases of aortic obstruction.

PERICARDIAL DILATION AND ADHESION.—EXHIBITED by Dr. J. T. ESKRIDGE. Exhibited by Dr. J. T. ESKRIDGE. Dr. Eskridge said that in this case the physician making the autopsy actually considered the specimen to be one of heart rupture. The patient was an athletic young man, and perfectly well until a few days before he sought medical advice. He was under treatment for only twenty-four hours, suffering from cardiac pain and great prostration. He died, suddenly and unexpectedly, when no one was near him. The attending physician, who made the post-mortem examination with no professional assistance, reported effusion in both pleural cavities, the pericardium distended with thin, non-coagulated blood, and a rupture of the left ventricle. Dr. Eskridge said that a careful examination of the heart, peri-

cardium, adjacent glands, and portions of the larger bronchi showed marked evidences of pericarditis and pleuro-pericarditis. The pericardium was adherent to the lower third of the heart, but the adhesions were recent and easily severed. The heart was not much enlarged, its valves were nearly normal, and its muscle firm. No rupture was found. He believed that the case was one of pleurisy and pericarditis with effusion, death taking place suddenly from mechanical interference with the heart and lungs. He thought that the most plausible explanation of the doctor's mistake in calling it a case of cardiac rupture was that, when severing the blood-vessels around the heart, blood flowed into the pericardium and mingled with the serous effusion. He did not think that a firm, non-fatty heart could rupture itself by its own contractions. If the pericardium was filled with effusion, in that instance it taught a lesson of far more practical value than a case of cardiac rupture under similar circumstances would. It was evident, if the pericardium should be attached to the apex of the heart in a case of pericardial effusion, in which operative interference was determined upon to free the heart's action, a thrust of the trocar into the pericardium would greatly endanger the ventricular walls.

SEVERAL SPECIMENS OF EYES ENUCLEATED ON ACCOUNT OF SYMPATHETIC IRRITATION IN THE OTHER EYE, OR FOR FEAR OF ITS DEVELOPING.—Exhibited by DR. LITTLE. Sympathetic irritation and sympathetic ophthalmia are the only two forms of the sympathetic diseases of the eye that afford an opportunity for pathological study, and in these cases only the enucleated eye can be investigated; just what are the conditions in the eye protected by the enucleation of the other eye, primarily at fault, must remain uninvestigated; if full restoration of the function of vision is attained in the one sought to be protected by the enucleation of the fellow-eye, great satisfaction only is felt. Less and less opportunity is being afforded of studying the condition of an eye enucleated for the presence of sympathetic ophthalmia in the other eye, since merely the sympathetic irritation of the sound eye impels the surgeon to enucleate the primarily affected eye before true sympathetic ophthalmia asserts itself. The portion of the eyeball which renders liable the development of this affection when diseased is so well known that not even sympathetic irritation should be allowed to develop, as an early enucleation will prevent it. Enucleation of the primarily diseased eye when true sympathetic ophthalmia is present in the other eye is now questionable, as, after all inflammation has subsided under treatment, surgical procedures upon the primarily affected eye may afford the best results for visual purposes. A recent experience would bear him out in this statement: the patient refusing the advice of a former medical attendant, and also his own, after two months, suddenly developed sympathetic ophthalmia of the sound eye. Enucleation was then too late. Now both eyes were becoming quiet, and he was in doubt which in the end would be the more available eye. A physician, recently under treatment for a severely traumatized eye, had refused the advice of two surgeons, and was now doing well, but the danger of a sympathetically irritated eye was constantly before him. The pathological investigation was, then, mainly restricted to eyes enucleated before or after sympathetic irritation had developed in the other eye, as results showed that under such circumstances full protection to the remaining eye was afforded. Investigation of eyes enucleated when sympathetic ophthalmia of the other eye was present might explain the cause of the trouble in the remaining eye, but there was so much damage done to both that our knowledge only makes us the more desirous to prevent these conditions from arising, and, in the multiplicity of conditions, the principal cause is lost. When enucleation to forestall sympathetic irritation or ophthalmia was done, or when the operation was performed, sympathetic irrita-

tion just beginning or present, the eyeball removed was in a much better state to examine, and more light could be thrown on the cause of sympathetic irritation, since severe inflammatory processes cloud the change from sympathetic irritation to that of sympathetic ophthalmia, and the pathological study was more difficult. His collection contained only one specimen enucleated when sympathetic ophthalmia was present, and, in this case, there was a double acute glaucoma with sympathetic iritis. At this time he only desired to exhibit some specimens of eyes enucleated for the protection of the fellow-eye from sympathetic irritation, or in which it was already beginning or developed, and in these cases good and permanent results have been attained. Four of these cases were due to traumatism; the fifth was of an inflammatory character. All but one of the traumatic cases had the fellow-eye affected, and the examination of the enucleated eye in the exceptional case justified the operation. In two cases the sound became affected shortly after the injury to the enucleated eye. In one case no irritation until forty years had elapsed since the accident to the enucleated eye. In one non-traumatic case there were repeated attacks for a series of years of irritability in the sound eye, until the pain in the diseased eye and the disturbance of the sound eye compelled operation. In the remaining traumatic case, for twenty years the uninjured eye was unaffected, except rendering the myopia more progressive, which rendered an operation imperative for its arrest and to prevent the outbreak of sympathetic ophthalmia later in life. The patients were aged, respectively, three years, forty years, forty-seven years, fifty years, and seventy years. Three of the patients were males, and two females. In four cases the left eye was enucleated, in one case the right. In every case the injury or disease involved, directly or indirectly, the ciliary body, and, where the crystalline lens remained *in situ*, or the sclerosed tissue impinged most markedly on the ciliary region, the irritation progressed most rapidly in the other eye. Where the crystalline lens was dislocated with weakening of the sclerotic tissue, no irritation appeared for forty years in the other eye. In one case with dislocation of the lens and detachment of the retina and choroid, no irritation had appeared at the end of twenty years in the other eye. In those cases where the iris became entangled in the cinctrix, sympathetic irritation of the other eye developed most rapidly, in one instance the lens becoming cataractous in the sound eye, while that of the injured one was either absorbed or lost at the time of accident. In short, was it not to injury of the ciliary nerves, with their varied function, and to the damage done to the tissue, in which they are imbedded in the different divisions of iris, ciliary body, and choroid, that we were to look as the cause of sympathetic irritation in the fellow-eye, and of these the ciliary body and nervous structures in it, with or without involvement of the iris, as the principal part involved? When sympathetic ophthalmia arises in the sound eye, could it not be traced to inflammatory processes added to the irritation of the ciliary nerves and involving the iris, ciliary body, and choroid? How far the retina and optic nerve participate in sympathetic irritation it was difficult to say; only we find that in sympathetic enucleation for sympathetic irritation the fellow-eye regains the full function of sight. In sympathetic ophthalmia, however, the involvement of the nerve and retina was a more important factor, and the fellow-eye was not so likely to be restored to full function of sight, as the condition in the enucleated eye and the one affected were more serious on account of marked inflammatory processes. [Dr. Little then gave in detail the histories of his cases, but, all essentials having been already given, their publication will be delayed until the next volume of the proceedings of the society appear.]

STAB OF THE PERICARDIUM, DIAPHRAGM, AND LIVER.—Exhib-

ited by Dr. STRITTMAYER. The specimens were removed from a German laborer, aged sixty-two, a patient, who was admitted July 16, 1882, in the surgical wards of St. Mary's Hospital, under Dr. Mears. He had been laboring for some days under a mental delusion, and, after writing a clear, intelligible letter to his wife and family in Germany, stabbed himself several times with a clasp-knife in the right side of the chest, notwithstanding all efforts of the bystanders to prevent him. He was at once taken to the hospital, and, on admission, was much excited, with a rather flushed face, but little shock, and struggled to escape from the punishment of his supposed crime. Examination showed two wounds: one over and reaching down to the cartilage of the sixth rib of the right side about one and a half inch from the sternal border, and about two inches in length; the other, half an inch from the border of the sternum, and severing from it the cartilages of the seventh and eighth ribs. Closer examination of this wound showed that there were two openings through the costal cartilages about a line apart, the outer passing downward, outward, and backward; the inner, in a direction inward, downward, and backward. Through these openings air occasionally passed when the patient respired violently when struggling, causing a high-pitched, sucking, and blowing sound. Slight bleeding took place, and that from the integument only. Physical signs everywhere normal except over the lower part of the right lung, where increased resonance was noted, and, on heavy percussion, a kind of "cracked-pot sound" was elicited. Auscultation revealed diminished breathing sounds over the upper part of the right lung, while respiratory sounds were entirely absent over its lower portion. Heart's action rapid and irregular. Heart sounds feeble, especially the first. Pulse 112, respirations 42 and shallow. There was no sign of internal hemorrhage. Both during inspiration and expiration, when the head and shoulders were raised, and he inspired deeply, a peculiar, high-pitched, blowing sound was occasionally heard a little to the left, and below the ensiform cartilage. It did not resemble the sounds produced by gas in the stomach or bowels. Antiseptic dressings were used, and morphia given, but he slept little, although nothing was complained of beyond a burning sensation beneath the sternum. The next morning he was calmer, rational, felt pain only during inspiration, and altogether breathed more easily than during the night, although the physical signs remained the same. The abdomen was tympanitic, the pulse full and moderately strong, 92 per minute, respirations 32, and expiration labored, with groaning. Temperature 101.6°. During the next night grew worse, with restlessness, poor sleep, followed in the morning by cutting pains in the chest at each inspiration; anxious, pinched face, and considerable anxiety as to his condition. Friction sounds were now heard over the whole of the left chest, and in the right side from the apex to the fourth rib. Pericardial friction sounds were also heard. Pulse 100, full and hard; respirations 48, with rapid, jerky inspiration, abruptly terminating, to be followed by a forced, prolonged groaning expiration. Temperature 103.2°. Evening pulse 120, respirations 44, temperature 103.2°. During the next twenty-four hours all the symptoms, physical as well as rational, of effusion into the pericardium and both pleuras developed, but, although the abdomen was tympanitic, no signs of effusion were detected. Pulse in evening 120, irregular, intermitting; respirations 40, temperature 101.8°. Had a bad night, and next morning seemed much prostrated, with a feeble, occasionally intermitting pulse of 120 per minute; temperature 102.8°; respirations 40, labored and shallow. Low, muttering delirium now set in, he sank rapidly, and died at 2 P.M. of the 20th, with a temperature of 105.5. [The surface temperature record, not showing anything of very decided interest, is omitted.]

Section cadaveris.—Brain: pia mater adherent, thickened in

patches, and opaque, especially on either side of the vessels, which were filled with dark blood over the upper convex surface of the left hemisphere. There was a slight amount of serous effusion in the subarachnoid space. The ventricles contained a small amount of serum. Chest: on raising the sternum, the right pleural cavity was seen filled with a thick, fatty-looking effusion, with some bands of recent lymph extending from the lung to the chest-wall. The apex of the lung was quite firmly adherent to the chest wall. The anterior surface of the lung was covered to the depth of one quarter of an inch with soft, grayish-yellow lymph. A portion of the back part of the inferior lobe was consolidated. The left pleural cavity was only about half filled, with the same thick layer of lymph and adhesion of the apex that was noted in the right lung. No part of the left lung would sink in water. The pericardial sac was distended with fluid, and both upon its inner surface and upon that of the heart was an abundance of lymph connecting the two surfaces by drawn-out bands of the same. There was a large chicken-fat clot in the left ventricle, extending about six inches into the aorta. The right ventricle was filled with blood, with a small clot extending into the pulmonary artery. Examination showed that while there were but two penetrating wounds externally, the knife must have been thrust in repeatedly after partial withdrawal, as there were three openings through the diaphragm, penetrating the liver to the right of its suspensory ligament, and one traversing the lower part of the pericardial sac and entering the left lobe of the liver for about one inch. The other liver wounds were one quarter, one half, and one sixth of an inch deep. There were no traces of peritonitis, although about two ounces of serum was present, probably escaped from the pericardial sac through the wound. The liver wounds did not gape, were ununited and surrounded for about an inch in every direction by a brownish-yellow discoloration. The liver weighed sixty-two ounces; spleen enlarged and soft; other organs healthy. [Owing to want of space, the remarks of Strittmayer have been omitted, to appear in the next volume of the society's Transactions.]

Remarks by Dr. MEARS: I was much interested in this case. During life, the symptom of wound of the diaphragm and of the liver were markedly absent, while those of injury of the pericardium and pleura developed as the interval after the receipt of the wounds increased. The external wounds gave little indication as to the direction taken by the knife after puncturing the thoracic cavity, and, as shown by the post-mortem examination, no information as to the extent of injury inflicted. The absence of symptoms of injury of the diaphragm may be explained by the fact that the wounds were in the tendinous portion of that muscle, and, being small, did not interfere to any great extent with its function in respiration. In injuries causing laceration of the muscular fibers attached to the ribs, dyspnea occurs as a prominent symptom by reason of the impairment of the respiratory duty of the muscle. Moreover, the symptoms may have been masked by those referred to the injury of the pericardium, as in wounds of both of these structures dyspnea is a prominent symptom. The knife, in one of the thrusts, passed through both and involved them in a common injury. The only explanation I can offer of the production of a sucking sound, or rather suction sound, which was heard under the ensiform cartilage, is that it was occasioned by the passage of air, during respiration, through the openings in the diaphragm, the air entering primarily the lung cavity through the external wound. The fact that the air did not pass in and out of the external wound during the act of respiration afforded good evidence that the lung was not wounded. The wounds of the liver were of such character as to make little or no impression beyond what might occur as the result of injury to the coverings and superficial portions. Puncture of the liver with a thrust is a frequently per-

formed with a view of evacuating fluids. Instances are reported in which no fluid has been found and no harm has been inflicted by the tapping. Extensive lacerations, the result of gun-shot wounds or rupture following falls, produce characteristic symptoms of shock and internal hæmorrhage.

SECONDARY SARCOMA OF HEART, LUNGS, AND GALL-BLADDER FOLLOWING PRIMARY AMPUTATION FOR DEPOSIT IN THE FEMUR.—Presented by DR. WILLARD. The specimens exhibited were the heart, lungs, and gall-bladder of a female patient, aged twenty-one, whose right thigh had been amputated four months previously for a spindle-celled sarcoma of the lower end of the femur. The apex of the right ventricle was infiltrated with a sarcomatous mass which extended into a cavity among the columnæ carneæ, forming an irregular-shaped body occupying one fifth of the space. The walls were softened, and but little of a muscular fiber was to be seen at the apical region. The diseased tissue was very soft, and easily detachable, rendering its propulsion into the lungs a matter of exceeding probability at each heart-beat. The walls above the mass were natural in appearance and in thickness. The valves showed no evidence of disease on either side of the heart. The left ventricular and both auricular walls were healthy. The disease had not reached the visceral layer of the pericardium, and there was no abnormal effusion in the cavity of the sac. The septum ventriculorum was not involved. That numerous particles had been swept into the lungs was very evident when these organs were examined. At a large number of points in either lung were to be seen white masses varying in size from that of a pin's head to that of an English walnut. Some of these were dense, others were undergoing softening, and in nearly every instance the lung substance surrounding was so disintegrated that the mass seemed to be in a cavity containing a drachm or more of sanguinolent fluid. A very moderate degree of pressure would cause a nodule near the surface to burst its pleural covering and give rise to an accident similar to the one which was found to have occurred near the right apex. At this point a large sarcomatous mass had excited a degree of inflammation sufficient to fasten the lung to the parietal pleura, and, one week before the patient's death, ulcerating through the serous covering had given rise to an internal hæmorrhage that was well-nigh fatal and gave the symptoms of sudden collapse noted in the history. This escaped blood was found in the right pleural cavity confined by adhesions chiefly to the upper portion of the chest. In the week which elapsed between the hæmorrhage and death it had coagulated, formed chicken-fat clots and other coagula weighing fully two pounds. The pleural cavity below the adhesions contained about two quarts of bloody serum. There was no consolidation of the lungs save around the diseased foci. The lungs had evidently acted as a complete strainer, and had prevented the passage of emboli, for liver, kidneys, spleen, and all other organs were healthy save one small spot in the gall-bladder. The brain was not examined. The primary disease in the femur had apparently resulted from traumatism, since no difficulty had existed previous to a severe fall upon the knee. From this time the pain on walking was continuous, and four months later there was decided enlargement of the external condyle and swelling in the popliteal space. The chief points of interest in the case were: First, the traumatism acting as an exciting cause. Second, that the physician who first saw her detected neither fracture nor luxation, nor anything beyond contusion of the joint. Third, the appearance, at the end of four months, in the popliteal space, of a pulsating tumor which presented a decided bruit, but no thrill. This was due to the lifting of the artery from its bed by the sarcomatous mass. Fourth, the non-involvement of the knee joint, although the nodules had pushed forward the synovial membranes between the condyles posteriorly. The articular

cartilage of the femur was intact, although the bone-tissue immediately beneath it was extensively diseased. Fifth, the return of the disease, not in the stump, but first in the right ventricle, and to failure in circulation and great prostration, which came on from four to six weeks after the amputation, and without anything in the condition of the stump to warrant such depression. The patient seemed in articulo mortis, yet there was no pain and no dyspnea; only a feeble, rapid heart action, accompanied by low delirium and weakness. There were no valve sounds audible. These symptoms were due, as shown post-mortem, to the deposit and development of the sarcomatous mass in the heart. Nature, however, gradually accommodated herself to the new growth, and the patient rallied for a time, so as to be able to walk on crutches, eat heartily, and consider herself in good health. She got fatter, and only slight dyspnea on exertion, with three or four coughs a day, remained to indicate recurrence of the disease. Sixth, a sudden, causeless as to exertion, profuse hæmorrhage from the collapse, incident to which she rallied and lived one week, with respirations 30 to 36, pulse 130 to 140. Seventh, the primary and consecutive growths showed a preponderance of spindle cells, while the secondary nodules were composed chiefly of round cells. Eighth, the post-mortem examination throws great light upon the clinical symptoms, while the great rarity of sarcoma of the heart makes it important to note that there was never any angina pectoris. In Dr. Ingram's report of a case called Carcinoma of the Heart, in the Transactions of this society for 1877, the only case ever presented to this society, angina pectoris was indicated as one of the diagnostic points. In the report of the Committee on Morbid Growths, Dr. Ingram's specimen was shown to be really an alveolar sarcoma. Secondary sarcomatous growths of the heart are mentioned by various authors, but the histories give no clinical signs of the growths. Dr. Barton said that, in regard to traumatism causing morbid growths, he considered that they probably had no more causative effect than acting as exciting causes. Dr. Formad asked if the exact nature of the primary growth was known, whether it consisted of round or spindle cells, since it has been stated that the spindle-celled variety never form metastases. Dr. Seiler replied that the primary growth consisted of both round and spindle cells. Dr. Shakespeare agreed with Dr. Barton as to the origin of the primary growth. He did not think that injuries were anything more than exciting causes in those predisposed to such growths. The case presented a typical example of the method of metastasis; we have the growth first developing at the knee, whence particles were carried by the veins to the heart, became there lodged, and develop into a tumor, which forms a new center from which microscopic emboli are carried by the blood-current into the lungs, where they lodge, and grow into the nodules seen in the specimen. Metastasis of sarcoma occurs by means of the blood-current, while that of carcinoma takes place through the lymphatics. Dr. Formad could see no other cause for the tumor than the injury of the knee, previous to which the patient had never shown any symptoms of disease of the joint, while shortly after receiving the injury the tumor appeared. The tumor may not necessarily be malignant; there is an inflammation and the formation of cells; the malignancy will depend upon the looseness of the cells and the facility with which they can be transported.

DR. C. R. MILLS then read a paper on THE BRAIN IN EPILEPSY, which, not admitting of abstract, will shortly be published in full.

DR. BRUBAKER presented a specimen of TUMOR OF THE BRAIN, which, with the accompanying paper, was referred to the Committee on Morbid Growths, whose report, with the paper, will appear at some future time.

C. B. NANCREDE, M. D., *Recorder*.

Reports on the Progress of Medicine.

QUARTERLY REPORT ON GENERAL MEDICINE.

NO. XIII.

BY ALEXANDER DUANE, M.D.

PRIMARY ENDOCARDITIS.—In a paper read before the British Medical Association ("Brit. Med. Jour.," Nov. 11, 1882), Dr. A. J. Harrison, after detailing three cases of endocarditis, occurring without arthritic lesion, maintains that the occurrence of the disease in this way as a primary disorder is not very rare, especially in those predisposed to rheumatism. He is inclined with others to regard endocarditis as one of the regular symptoms rather than one of the frequent sequelæ of rheumatic fever. [It has been held (by Haskins) that the heart lesion is actually the initial feature of every rheumatic attack, and that its presence can always be substantiated by physical signs. And this author accordingly advocates counter-irritation over the heart as the only rational method of treatment in all fresh cases of rheumatism. Others, while acknowledging the constancy of the presence of roughened heart sounds in rheumatism, do not consider that this sign possesses the significance which Haskins assigns to it.]

THE ORIGIN AND NATURE OF TUBERCULOSIS.—A paper read before the New York Academy of Medicine by Dr. T. E. Satterthwaite ("Med. Record," Oct. 28, 1882) and the subsequent discussion show that a tolerable uniformity of opinion exists at present upon the subject of tuberculosis, at least in the minds of New York pathologists. The general conclusion was that pulmonary phthisis almost invariably implied pulmonary tuberculosis; that we had not yet sufficient grounds for believing in the bacillary and infective nature of tuberculosis, although there were some grounds for believing in its communicability by co-habitation; that, however, bacilli of a peculiar character were frequently to be made out in phthisical sputum; and, finally, that tuberculosis, however generated, was essentially inflammatory as far as its lesions are concerned.

In a scholarly paper ("Maryland Med. Jour.," Nov. 1, 1882), Dr. W. T. Conneliman reviews the different discoveries which have furthered the view that tuberculosis is an infectious disease, he himself being strongly of the opinion that this view is the correct one. In his own investigations he has been almost uniformly successful in discovering specific bacilli in tuberculous sputa.

Dr. H. F. Formad ("Phila. Med. Times," Nov. 18, 1882), while acknowledging that bacilli are regularly present in tuberculosis, asserts that they have no specific influence in causing the disease, although they may serve to aggravate its intensity. His own theory of tuberculosis is that individuals become tuberculous by virtue of a peculiarity of anatomical structure, consisting of a narrowing of the circumvascular lymph channels, and of their partial obliteration by cellular elements; that, in this condition of things, when inflammation takes place from any cause whatever, the inflammatory products, instead of being carried off by the lymph in the ordinary way and so eliminated, remain behind, degenerate, and form tubercles; and that these, by their pressure, induce necrotic changes in the surrounding tissues. The narrowing of the lymph spaces may be congenital, as in some species of animals and in some classes of men, or it may be induced by malnutrition, as in animals kept in confinement, or in cases of acquired tuberculosis in man. Tuberculosis may also be induced in persons with no tuberculous tendencies by a simple inflammation of the larger serous cavities; and Formad suggests that this may be due to the rapidity with which

absorption takes place in such cases, so that the lymphatic channels are overcrowded and their caliber is diminished.

NERVE-STRETCHING.—Dr. A. Ceccherelli ("Sperimentale," Sept., 1882), has published an extensive review of more than a hundred papers upon nerve-stretching. In discussing the subject in its physiological aspects, he asserts his belief that the results of the numerous experiments which have been made to determine the extensibility of nerves and the amount of traction force which they can bear are not applicable to the conditions existing in the living human body, and so can form no guide to the surgeon in estimating the degree of force which he can use in the operation. The pathological changes which have been observed after nerve-stretching consist chiefly of extravasations and of degenerative changes, affecting either the perineurion, the vessels of the nerve, or the ultimate nervous fibrils. The general effect of these changes is to produce diminution of sensory conductivity without impairment in capacity for motor impulses, unless the traction force is very great, when also disturbances may occur in the nutrition of the nerve and the tissues supplied by it. In what way this effect is brought about is a disputed point, some, with Vogt, referring it to local alterations in the circulation, or the relations to surrounding parts of the nerve itself or its peripheral branches, while others regard it as due to consecutive changes in the cord. The latter opinion seems entitled to the greater confidence, and is held by most observers. One argument in its favor is the bilateral character of the effects obtained after stretching the nerve upon one side. As to the operation itself, it may be done either without incision by forced extension of the limb, or in the ordinary way by exposing the nerve and employing direct traction. The amount of force to be used has excited much discussion. Some lay down the rule that in cases of paralysis moderate traction should be employed, but in cases of neuralgia, tetanus, and contracture, a considerable degree of power is to be exerted. The results of the operation in affections of the nerves themselves—in neuralgias, contractures, and peripheral paralyses—are very favorable. In locomotor ataxia no decisive results have as yet been obtained. In other central nervous lesions the propriety of the operation is doubtful. In tetanus it may do good by diminishing the excitability of the afferent nerves.

CHYLURIA AND THE FILARIA SANGUINIS.—Dr. W. Havelberg ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," lxxxix, 2, 1882) describes a case of *chyluria* in which death occurred with symptoms of increasing inanition after the discharge of chylous urine had persisted six months. In this case, from the results of autopsy, there appeared to exist a thrombosis of one of the larger branches of the thoracic duct, with subsequent chylous ascites and dilatation, with rupture of the lymphatics in the bladder-walls. In the blood, and occasionally in the urine, the *filaria sanguinis* was found during life, and the author presents several illustrations of the parasite, and a description agreeing in general with that given by other observers. The animal, which, as it occurs in this situation, is the embryonic form of a nematode worm, whose adult form is found in the dog, has a body of about the diameter of a red blood-corpuscle, and a length of a hundredth of an inch or more, and is provided with a membranous envelope attached closely to the cephalic but loosely to the caudal end. In some specimens there appears to be a canal running through the entire length of the animal. Havelberg follows Manson's description of the development of the parasite, and of its transmission by means of the mosquito.

We have had the opportunity of examining the material reported by Dr. Abbe in this journal several years ago. In this case *filarie* were present in the blood, although, following the general rule, they were found during the night only. The symptoms ran a very chronic and intermittent course, the most

marked, in addition to vesical tenesmus due to the presence of clots of blood and fibrin in the bladder, being boulimia, thirst, emaciation, and a tendency to furunculosis—a combination of symptoms seen so frequently in diabetics. All varieties of treatment—medicinal, dietetic, and topical—were tried, but, as Havelberg remarked in regard to his own case, no treatment seemed of any permanent efficacy. — The autopsy in Havelberg's case revealed a condition very like that found in a case of Dr. Stephen Mackenzie's, in which all the abdominal and thoracic lymph channels were enormously dilated and the thoracic duct was occluded for a portion of its length. In Mackenzie's case, in addition, there were found in a clot taken from the right auricle of the heart countless *adult* filariæ projecting in every direction "like long curling strands of whip-cord" ("Brit. Med. Jour.," May 20, 1882.)

TRISMUS OF CEREBRAL ORIGIN.—M. Lépine ("Rev. de méd.," Oct., 1882) gives the details of a very interesting case, in which the only paralytic symptom during life was a persistent tonic spasm of the muscles closing the lower jaw (trismus), and in which autopsy showed a clot as large as a small pigeon's egg upon the left side of the brain, immediately below the gray matter of the insula, and at the base of the ascending frontal convolution. This is almost exactly the location of the center which Ferrier discovered in the monkey, irritation of which produced masticatory spasm. Observations of similar character have before, although rarely, been made; and some of these the author cites.

TRICUSPID INSUFFICIENCY.—M. François-Franck ("Progr. méd.," Sept. 30, 1882) has, by specially constructed valvulotomes, succeeded in producing tricuspid insufficiency artificially in animals, and has thus been enabled to observe the train of secondary symptoms. The latter are thus classified by the author:

1. Changes in the venous circulation. Evidenced by jugular systolic pulsation, dilatation of the veins of the thorax, and hepatic pulsation.

2. Changes in the heart itself. Development of a systolic bruit, whose pitch is in inverse proportion to the extent of the lesion; increased frequency of the cardiac action; diminution in the arterial pressure.

3. Respiratory changes. Increased frequency of the respiration.

4. After a longer or shorter time, the phenomena of general venous stasis—ascites, anasarca, albuminuria, etc.

TRICUSPID MURMURS HEARD AT THE APEX.—M. P. Duriozicz ("Union méd.," Nov. 12, 26, 1882), after a careful review of the literature of tricuspid murmurs from the time of Lancisi and Laënnec down, and after reciting two cases which he himself had observed, concludes that a tricuspid regurgitant murmur can be heard over the entire anterior surface of the heart, the points of maximum intensity being sometimes at the xiphoid cartilage, sometimes at the cardiac apex, and it may be heard at the latter spot only. It is not, however, transmitted to the axilla, nor is it heard in the back. It is not necessarily associated with venous pulsation.

AMYGDALITIS AND ALBUMINURIA.—M. Laure (*ibid.*, Oct. 17, 19, 1882) signals the not infrequent occurrence of an albuminuria, transient in most cases, permanent in others, in conjunction with the various forms of tonsillar inflammation; and, having also found bacteria in the urine in these cases, he suggests that in this and in other acute diseases an accompanying renal inflammation may be dependent upon direct irritation of the uriniferous tubules from the presence of these organisms. [We can recall one case in which we have observed this connection between amygdalitis and albuminuria, the amount of albumin being in direct ratio to the severity of the constitutional symptoms. The possible bacterial origin of the nephritis which

complicates the acute infectious diseases had already been asserted by Eckstein.]

GLYCOSURIA.—Dr. Ord ("Brit. Med. Jour.," Nov. 25, 1882) has observed twenty-two cases of glycosuria in old men, all of which were characterized by the comparative absence of polyuria and of the graver symptoms of the disease, such as profound emaciation, great thirst, etc. This peculiarity which distinguishes the diabetes of old men from that of youthful subjects confirms the author in the belief that glycosuria is an affection of multiple nature. In all of Ord's cases the passage of saccharine urine occurred as a concomitant, either of nervous disease or disturbance (in twenty cases), of gout (in eight cases), of nitrogenous metamorphosis; boulimia is less prominent; the characteristic dryness of the skin may be replaced by sweating; there is a considerable degree of muscular wasting, which is frequently masked by an increased deposit of fat in the subcutaneous tissues; the visual disturbances are more refractory, and mental disorder is more frequent. A chronic form of cerebral softening is a very common complication, and depends, apparently, upon nutritive alterations in both the tissues and the supplying vessels, due to impoverishment of the blood and its overloading with uric acid. Other complications are pulmonary phthisis, pneumonia, carbuncle, gangrene of the extremities, Bright's disease, and the formation of vesical calculi. Changes in the liver are more constant than in ordinary diabetes, and an atrophic cirrhosis may exist. In the treatment an essential factor is a restriction in the use of the strong liquors which are permitted in ordinary diabetes. The dietetic management of the affection, together with well-regulated exercise, constitutes the treatment; although the author also regularly prescribes the bromide of potassium. The prognosis in uncomplicated cases or of albuminuria, if this treatment is faithfully carried out, is good. In seven cases there was a clear history of mental strain or worry; in three, glycosuria was associated with hypochondriasis, and in three others it occurred in connection with locomotor ataxia. In three instances it occurred as an alternate symptom with attacks of angina pectoris. The author suggests that cases of glycosuria associated with gout may be regarded as dependent upon a gouty affection of the liver, with resulting functional disturbance of the latter organ.

M. Bouchardat ("Bull. gén. de thérap.," Oct. 15, 30, 1882) discusses at length that form of diabetes which is associated with an excessive excretion of uric acid (*glyco-polyurique*). It occurs in advanced life, seldom before the age of fifty, and particularly in those who have indulged freely in the pleasures of the table and who have lived sedentary lives. It differs from ordinary diabetes in several regards. Polyuria is less marked and the urine is of higher color, and contains the products in relatively greater amount, or it appears to be dependent upon dietetic errors or the abuse of alcohol. [Etiologically, the diseased condition which Bouchardat calls *glyco-polyurique* seems to be a combination of ordinary diabetes and gout, and, in its multiple nervous manifestations, is quite comparable to the form of glycosuria which Ord describes. That the gouty element is the predominant factor is apparent from the account given by both of these authors, and, as Bouchardat indicates, treatment is most properly addressed to the removal of this factor. Ord's idea, that the glycosuria in such cases is due simply to gouty derangement of the liver, possesses considerable plausibility, and, if true, furnishes another evidence of the Protean character of the gouty dyscrasia.]

THE DIAGNOSIS OF HYSTERICAL PARALYSIS AND ANTERIOR POLIO-MYELITIS.—Dr. A. H. Bennett ("Lancet," Nov. 18, 1882), insisting on the difficulty, and in some cases the impossibility, of making a diagnosis between hysterical paralysis and that produced by polio-myelitis anterior, says that we have two diag-

nistic criteria, which, taken together, will enable us to make the distinction in every case. These are the absence of the reflexes, and the early abolition of electrical reaction in the paralysis of polio-myelitis.

MYXEDEMA.—Dr. A. McL. Hamilton's article ("Med. Record," Dec. 9, 1882) is a valuable summary of the principal papers upon the subject. He is inclined to the view that the disease is dependent upon a "lesion primarily of the bulb with secondary extension to the postero-lateral columns of the spinal cord and the spinal sympathetic ganglia." He thinks that an associated renal disease is the result and not the cause of the myxœdema.

THE TREATMENT OF DIPHTHERITIC SORE THROAT.—Dr. W. A. Jamieson ("Edinb. Med. Jour.," Dec., 1882), on the strength of one or two observations, strongly recommends in diphtheritic sore throat the local application of a saturated solution of boro-glyceride in glycerin, combined with the internal administration of salicylate of sodium.

INCONTINENCE OF FECES IN CHILDREN.—Dr. G. B. Fowler ("Am. Jour. of Obstet.," Oct., 1882) describes two cases in which incontinence of feces occurred without local lesion and under circumstances similar to those which obtain in incontinence of urine—undue reflex irritability, or loss of muscular tone due to systemic causes. The treatment consisted in attention to the general health of the patient, and in the administration of ergot. Recovery was complete.

THE TREATMENT OF DROPSY.—Dr. D. J. Leach ("Brit. Med. Jour.," Oct. 21, 1882) thinks that we are not justified in ascribing all cases of dropsical effusion to obstructed venous return or diminished urinary excretion, and that, therefore, not every case of dropsy is to be remedied by agents directed to relieving these faulty conditions. Other causes which may co-operate in the production of dropsies, and are more or less removable by treatment, are alterations in the quality of the blood or changes in the blood-pressure, defective innervation of the vessels or the circunvascular tissues, and structural alterations in the vessels and tissues. Of the agents aiming at the removal of the fluid, he puts the mechanical method by tapping in the first place, and in hepatic cirrhosis especially he recommends early and repeated partial tappings as the best method for arresting the disease. In puncturing for subcutaneous œdema, he prefers Southey's tubes as being less liable to cause irritation. When diuresis is resorted to, he employs digitalis or caffeine, holding them to be the most efficient of the vegetable drugs, and of somewhat superior efficacy to the salines.

THE SELF-LIMITATION OF PHTHISIS.—Dr. A. Flint (*ibid.*, Sept. 30, 1882), in a consideration of seventy-five cases of phthisis, which either ended in recovery or remained stationary for a number of years, found nearly half in which this favorable result could not be attributed to treatment, and in which, therefore, a tendency to self-limitation of the morbid process may be supposed to exist. This same tendency, he thinks, is seen in the discontinuous advance of an ordinary case of phthisis, which, it appears, repeatedly dies out and is revived. He is further inclined to the belief that many cases of incipient phthisis, which are diagnosed as such by the physician, have their progress permanently arrested by this same process of self-limitation. In proof of this, he alleges the results of numerous autopsies of subjects who have given no phthisical symptoms for many years, but in which the products of old tuberculous inflammation are found encapsulated in the lungs.

ASCUITATION OF THE TRACHEA AND MOUTH.—Dr. D. Drummond (*ibid.*, Oct., 21, 1882) finds ascuitation of the trachea by means of a stethoscope, with the chest-piece inserted into the mouth of the patient, useful in the diagnosis of tracheal compression, particularly when produced by aortic aneurism, in

which case a systolic whiff is heard with each expiration. Percussatory percussion practiced on this plan gives valuable indications in pulmonary disease. Thus, in incipient phthisis a peculiar note is obtained, closely resembling "cracked-pot" resonance; in pleurisy a very short, high-pitched note is produced, very different from the lower-pitched, more prolonged, and much louder tone heard if pneumonic consolidation exists.

HEART DISEASE AND NEURALGIA.—M. P. ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," Oct. 7, 1882), cited cases in which neuralgic pains of the left upper extremity, of traumatic origin, were followed by the symptoms and the objective signs of cardiac hypertrophy, together with melancholia. In one instance a similar affection of the left lower extremity had a similar result.

FIBRINOUS OR HYALINE DEGENERATION OF TUBERCLES AND GUMMATA.—Among the degenerative changes to which tubercle and, according to Dr. M. Vallat ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," lxxxix, 2, 1882), gummata are subject, is the hyaline or fibrinous metamorphosis. This occurs chiefly in the spleen and lymphatic glands, and appears to take place by a process of thickening of the reticula of the morbid growth itself or of the surrounding glandular tissue, and by subsequent transformation of these reticula into a homogeneous, strongly refractive substance, while the meshes which originally existed in the tissues are converted into lacunae and canals filled with the débris of cells and with free nuclei. Vallat regards this form of degeneration as preliminary to caseous changes, since in tubercles a center of caseation is often found surrounded by a zone of the hyaline substance, and this again is enveloped by normal tubercle tissue.

Miscellany.

INDIAN ENTERIC FEVER.—Dr. R. H. Quill, Surgeon in the Army Medical Department, gives the results of his examination of the annual returns of the sick and wounded troops at Ambala Medical Station from 1875 to 1881. This station is centrally located and the mortality carried out by the "enteric fever." The returns of the battalions are arranged into tables, the following are the most striking facts: The death rate is 14 per cent. First position is taken to avoid exposure to wind at night. During the period mentioned, not one of 250 cases of enteric fever occurred among the troops. The believers in the climatic origin of cases of enteric fever in India very correctly point out that the principal sources of

this fever are young soldiers, with little Indian service; and that the older men, with an Indian service of four or more years, are rarely sufferers from it. Without gainsaying this observation, or attempting to account for it, Dr. Quill would simply say that, for a space of five years, Assirgarh has been occupied by successive batches of young and unseasoned soldiers without the occurrence among them of any type of fever other than the mildest form of ague. The climate of Assirgarh is no better than that of many other stations in the Bombay Presidency, where enteric fever is of only too frequent occurrence; but its isolated situation, and the nature of its surroundings, lessen to a very great extent its liability to faecal contamination of any sort; and herein lies the reason for the immunity it enjoys from the presence of enteric fever.—*British Medical Journal*.

NOCTURNAL ENEURESIS, TREATED BY VOLTAIC ALTERNATIVES.—Dr. Althaus writes to the "British Medical Journal" that, "in June, 1882, he was consulted in the case of a boy, aged fifteen, who had suffered from incontinence of urine during sleep ever since he was nine years of age. He had been treated with belladonna and other medicines without relief; and as he was about to enter a public school, where a continuance of this trouble might have been particularly annoying, the parents were very anxious that something more should be done. The boy's general health was good, but he was considered a nervous child, and highly sensitive. There were no ascarides, but he had a very long prepuce, which could only with difficulty be retracted. There was, however, no suspicion of masturbation. Treatment by electricity having been recommended, Dr. Althaus applied the middle-sized circular cathode over the region of the bladder, and the large oblong anode (five inches by two) to the lumbar portion of the spine. The current strength 2.50 milli-amperes for five minutes at a time. As after a few such applications no material benefit appeared to have been gained, he then added fifty voltaic alternatives produced in the metallic circuit. The night after this was free from the usual annoyance, and the boy has made an apparently uninterrupted recovery." Dr. Althaus prefers this method of treatment to injections of nitrate of silver, as recommended by Sir Henry Thompson. He believes that belladonna is of value when enuresis is distinctly caused by undue excitability of the bladder.

THE EFFECT OF TEMPERATURE ON REFLEX EXCITABILITY.—In a paper by Dr. W. T. Sedgwick, an abstract of which we find in the "Johns Hopkins University Circulars," the author points out that the work of previous experimenters, which seemed to show that indirect heating of the frog's heart diminished its functional activity, involves essential errors, inasmuch as the nutrition of the heart by a flow of blood through it was not properly taken into account. He also proves that the corollary from the work of those experimenters—viz., that indirect heating of the spinal cord (within the limits of its physiological working) might diminish its functional activity—has no sound experimental basis; and he shows that much more regard must be paid to the influence of temperature and of drying of the skin upon the reflexes of the frog than has been paid hitherto, if any satisfactory conclusions are to be reached.

THE ACTION OF DIGITALIN ON THE HEART.—Dr. H. H. Donaldson and Dr. M. Warfield, as the result of experiments on the slider terrapin (*Pseudemys rugosa*, Shaw), undertaken as a preliminary to investigations as to the action of the drug upon the heart of mammals, conclude, according to the "Johns Hopkins University Circulars": 1. When the heart is doing normal work, digitalin decreases that work. 2. There is a rough relationship between the size of the dose and the extent of the decrease. 3. With small doses the pulse rate is at first increased. 4. The diminution in the heart's work is much more dependent on the strength of the dose at any given time than on the total amount of the drug administered. A large amount given in several hours has much less effect than a smaller amount given in a few minutes. Therefore the theory that digitalin has a cumulative action lacks experimental confirmation.

THE POLAR EFFECTS OF INDUCTION CURRENTS ON NERVES.—A paper by Dr. Henry Sewall, abstracted in the "Johns Hopkins University Circulars," deals with the influence of very weak induction currents passing between one pair of electrodes on the irritability of the nerve,

as shown by variations in the extent of submaximal muscular contractions, due to stimulation by another pair of electrodes. The results prove that marked polar (analectrotonic and catelectrotonic) effects can be produced by induction currents.

INFECTIOUS DISEASES AND THE LOWER ORGANISMS.—Dr. W. T. Councilman, of Baltimore, assumes, according to an abstract of a recent paper given in the "Johns Hopkins University Circulars," that the infectious diseases are caused by the entry of a *materies morbi* into the organism. That this *materies morbi* is a living organism in every case appears to be proved by experiments which show that it is a substance which is insoluble and capable of increase. We know that it is a substance because it clings to inert objects, and can thus be transported from one place to another, or kept any length of time without losing its power; a blanket from a small-pox patient, for example, can be transported thousands of miles and then produce the disease. Chauveau's experiments with vaccine lymph and the experiments which Davaine made with the blood of splenic fever show that it is insoluble. Of all soluble poisons we know that their virulence decreases in a regular ratio with their dilution; on the other hand, no amount of dilution seems to take away entirely the infectious properties of the blood of animals affected with splenic fever, Davaine having succeeded in producing the disease after the blood was diluted 1,000,000 times. The disease, when produced by such diluted virus, differs not at all from that produced from the undiluted virus. That it has the power of increasing is shown from the fact that, having introduced one of the spores of the *Bacillus anthracis* into the circulation of a mouse, in a few hours the whole vascular system will be filled with the bacilli. Now, having an insoluble substance with this power of increasing, of growing, it must be a living organism; it is possible for a soluble substance in a purely chemical manner to produce its like, to increase, but, if a granule multiplies indefinitely, it must divide, and the divided pieces must grow. In quite a number of the infectious diseases we find, either in the blood or in the pathological lesions, a certain organism, and know that on inoculating animals with the tissues containing these organisms an identical disease will be produced. In order to prove that it is the organisms alone that are infectious it is necessary to isolate them completely from the tissues or fluids with which they are associated, and produce the disease by inoculation of the organisms alone. This can be done by the so-called pure culture, by growing the organisms outside of the body and transferring them from one nutrient substance to another until we know that we have them perfectly pure. In the case of splenic fever, tuberculosis, and some other diseases, this has been done, while in other diseases, although we always find a certain definite organism associated with the disease, the strict objective proof that the organism is the cause of the disease is wanting, because we are not able to produce the disease on the lower animals by inoculation of the isolated organisms, nor indeed in any other way. Animals show a perfect immunity to a number of our diseases. The benefits which we have derived, both in prophylaxis and in therapeutics, from these additions to our knowledge are great, and are daily increasing.

PATENCY OF THE DUCTUS ARTERIOSUS.—A recent number of the "Johns Hopkins University Circulars" gives an abstract of some observations, by Dr. W. H. Howell and Dr. F. Donaldson, Jr., on the form of the pulse wave and the mean arterial pressure in a dog with a patent ductus arteriosus. The dog was about to be killed, when it was noticed that its cardiac action was abnormal. Professor Donaldson, of the University of Maryland, examined the animal, and found the pulse rate greater and the cardiac impulse more marked than in normal dogs; also, the apex of the heart extended much farther to the left, showing marked hypertrophy. Over the whole cardiac region he observed a loud rasping cardiac murmur with the maximum of intensity over the base; also a slight murmur with the second sound. Subsequent experiments showed a normal arterial pressure, and no abnormality in sphygmographic tracings, except an unusually marked diastolic murmur. Professor McLane Tiffany made the post-mortem on the animal, and found that the ductus arteriosus had remained open, its caliber being at least equal to that of either pulmonary artery. It is a fact of much interest that with such free communication between the aortic and

pulmonary circulations so good an average arterial pressure as measured in the femoral artery) was maintained. It can only be explained by assuming: (1) a compensatory increase in the force of the heart-beat; (2) an increase in the resistance of the pulmonary circuit; or (3) an increase in the total bulk of blood in the body. Whichever of these agencies was the effective one, the case is one of great interest, as indicating the power of the animal body to adapt itself to unusual conditions of life. So far as the authors could discover, only one similar case was previously on record.

INTRACARDIAC PRESSURE AND PNEUMOGASTRIC INHIBITION.—Dr. Henry Sewall and Dr. Frank Donaldson, Jr., from experiments on frogs and terrapins, conclude, according to a summary in the "Johns Hopkins University Circulars," as follows: 1. When the whole heart is employed, increments of venous pressure, the arterial pressure being constant, weaken the cardio-inhibitory action of the vagus. Thus they confirm the results of Ludwig and Luchsinger. 2. Variations of intraventricular systolic pressure within wide limits have no perceptible effect on the activity of the vagus. 3. Variation of diastolic intraventricular pressure, when uncomplicated by simultaneous variation in auricular pressure, has no effect. They therefore conclude that changes of intracardiac pressure, when experienced by the ventricle alone, are without effect on the cardio-inhibitory function of the vagus. 4. Variations of pressure within the sinus and auricles, the ventricle being entirely separated from them, give the same results as when venous pressure is varied in the complete heart. 5. The effect of variations of pressure within the venous sinus, all the rest of the heart being excluded, is such that raised pressure diminishes the cardio-inhibitory action. The paper concludes with some general considerations on the manner in which the vagus exerts its inhibitory action upon the heart.

THE CORONARY ARTERIES AND THE SEMILUNAR VALVES.—In a recent number of the "Johns Hopkins University Circulars" we find an abstract of a report of certain observations on the mean pressure and the characters of the pulse wave in the coronary arteries of the heart, by Dr. H. Newell Martin and Dr. W. T. Sedgwick. The object of the authors was, by a critical experiment, to endeavor to settle the long-disputed point whether the aortic semilunar valves close the mouths of the coronary arteries during the systole of the left ventricle of the heart. If the valves act in this way, the pulse wave in the coronary arteries of the heart must differ essentially, both in form and in the period of its maximum intensity, from the corresponding wave in the carotid artery. Simultaneous tracings taken in a branch of the left coronary artery and in a carotid artery agree in every respect. Hence the Thebesius-Brücke doctrine as to the closure of the orifices of the coronary arteries during ventricular systole and as to the resulting "Selbststeuerung" of the heart must be abandoned.

SIR WILLIAM GULL ON SCIENTIFIC MEDICINE IN GENERAL PRACTICE.—In the course of an address delivered on January 17th, before the Metropolitan Counties Branch of the British Medical Association, on the subject of the Collective Investigation of Disease, Sir W. Gull observed: "It will be admitted that, had we leisure, proper means at our disposal, and, from previous training, a fitness for exact observation, we should find in general practice one of the most valuable fields of pathology, as here, and here only, we have before us the earliest signs of departure from health, and the only opportunities for tracing the course of a disease from its beginning to its end. Having passed many years in hospital and private practice, I have come to see that experience gained in the latter is necessary for the correction of that acquired in the former, especially as helping toward a truer pathology. It will, perhaps, and naturally, be objected that it is almost impossible to organize for any useful purpose the labors of men already overburdened by the cares and fatigue of practice; and that there is neither time nor fitness for delicate inquiries on their part. Admitting that this objection is valid, it may be urged in reply that it need not be insuperable. It can not be denied that when we see the meaning of the apparent trifles which in practice would otherwise oppress and worry us, our burden is thereby much lightened, and that nothing could encourage us more than to feel that even one daily observation recorded was adding to our general store of knowledge, and making the path

of practice more easy. There is no task to the mind greater than the sense of work done; and our journey is likely to be made shorter, as it certainly will be easier, if the way is illuminated. We, indeed, owe it to those members of our profession who are admittedly overwhelmed by the apparently senseless details of their work, to promote a movement like collective investigation, the object of which is to bring order into chaos, and to help them to stamp a scientific value upon facts hitherto only burdensome. If we compare the unflagging interest of any pursuit where the aim is high and clear with the tediousness and wearisomeness felt when working in the dark, we shall readily admit that we are actually lightening the burdens of practice by thus adding to them, and by giving some portion of them a sense and meaning. It is the spirit of a man which enables him to do his work lightly and cheerfully, and he will certainly be helped in this by a combination with fellow-workers on the same subject."—*British Medical Journal*.

THE USE OF THE MULLEIN PLANT IN THE TREATMENT OF PULMONARY CONSUMPTION.—F. J. B. Quinlan, M.D., M.R.I.A., F.K.Q.C.P., Physician to St. Vincent's Hospital, Dublin, observes that "from time immemorial the *Verbascum Thapsus*, or Great Mullein, has been a trusted popular remedy in Ireland for the treatment of phthisis." After relating seven cases where it proved of benefit, he concludes: "I have set down the above cases simply in the order in which they occurred, and with no view of supporting any preconceived idea. These cases, although too few to justify any general conclusion, appear to establish some useful facts. The mullein plant boiled in milk is liked by the patients; in watery infusion it is disagreeable, and the sucus is still more so. The hot-milk decoction causes a comfortable (what our Gallie neighbors call *pectorale*) sensation, and when once patients take it they experience a physiological want, and, when the supply was once or twice interrupted, complained much in consequence. That it eases phthisical cough there can be no doubt; in fact, some of the patients scarcely took their cough mixtures at all—an unmined boon to phthisical sufferers with delicate stomachs. Its power of checking phthisical looseness of the bowels was very marked, and experiment proved that this was not merely due to the well-known astringent properties of boiled milk. It also gave great relief to the dyspnoea. For phthisical night-sweats it is utterly useless; but these can be completely checked by the hypodermic use of from one eightieth to one fiftieth of a grain of the atropia sulphate, the smaller dose, if it will answer, being preferable, as the larger causes dryness of the pharynx, and interferes with ocular accommodation. In advanced cases, it does not prevent loss of weight, nor am I aware of anything that will, except koumiss. Dr. Carrick, in his interesting work on the koumiss treatment of Southern Russia (page 213) says: 'I have seen a consumptive invalid gain largely in weight while the disease was making rapid progress in her lungs, and the evening temperature rarely fell below 101° Fahr. Until then I considered that an increase of weight in phthisis pulmonalis was a proof of the arrest of the malady.' If koumiss possesses this power, mullein clearly does not; but, unfortunately, as real koumiss can be made from the milk of the mare only and as it does not bear traveling, the consumptive invalid must go at least to Samara or Southern Russia. In pre-tubercular and early cases of pulmonary consumption, mullein appears to have a distinct weight-increasing power; and I have observed this in several private cases also. Having no weighings of these latter, however, makes this statement merely an expression of opinion. In early cases, the mullein milk appears to act very much in the same manner as cod-liver oil; and, when we consider that it is at once cheap and palatable, it is certainly worth a trial. I will continue the research by careful weighings of early cases; and will further endeavor to ascertain whether the addition of mullein to the cultivating solution prevents the propagation of the phthisical bacillus."—*British Medical Journal*.

TREATMENT OF DYSENTERY.—Mr. F. E. Ross, M.R.C.S., observes that, at the present time, when dysentery is very prevalent, especially among those who have returned from the East, a ready and reliable remedy that may mitigate the suffering of so fatal a malady will be hailed with gratitude. The plan he has used with most success is the following: First, having placed the patient between warm blankets, a pint and a half of warm water, at a temperature of 90° Fahr., is injected.

This is seldom retained longer than a few minutes, but is pronounced very grateful to the patient. When the water has soothed the mucous membrane of the colon and rectum, and brought away any *effete* matter, two ounces, by measure, of the following enema is administered with a gum-elastic bottle: \mathcal{R} Quinine sulphate, ten grains; compound tincture of camphor, four drachms; decoctum amyli, to two ounces. Mix, and, when about milk-warm, inject, which is generally retained; but, if ejected, it may be repeated after an hour or two. This has been found of great service, and very grateful to the patient; the effect is like magic. If griping pains be felt over the region of the epigastrium, half-drachm doses of chlorodyne, in some aromatic water, mint, caraway, or aniseed, should be given. The diet, of course, should be of the most soothing kind: jellies, isinglass, linseed, toast, and barley-water *ad libitum*. Ipecacuanha appears of little service, and Mr. Rawle has discarded it from his treatment. Warm turpentine stupes, on warm flannels, over the hypogastrium prove very beneficial.—*British Medical Journal*.

HYDATIDIFORM DISEASE OF THE CHORION.—Mr. Edward Stephens, M. R. C. S., of Ilminster, writes to the "*British Medical Journal*" that "on September 7th he was sent for by a midwife to attend Mrs. C., who was flooding. On his arrival, the hemorrhage had stopped. On making an examination, the uterine sheath was not sufficiently dilated to be able to ascertain its contents. On passing his hand over the abdomen, he remarked to the midwife how unusually circular it was. On the following afternoon he was again hastily summoned, and found the woman had lost much blood. On making an examination, he found that, by a little manœuvring, he could insert his hand into the uterus; and he vividly remembered how astonished the midwife and Mrs. C. looked when he informed them that it contained no child. In fact, Mrs. C. stoutly declared that she had felt the child many times, and that, being the mother of thirteen children, all living, she ought not to have been mistaken. After administering a full dose of ergot, some sharp uterine pains followed—soon expelling a mass, which, when collected, filled three ordinary-sized chamber-utensils. After this jelly-like mass had been expelled, she rapidly recovered, and made an interrupted recovery."

COMPOUND FRACTURE OF THE FEMUR, ERYSIPELAS, PYÆMIA; AMPUTATION OF THE THIGH; SUBSEQUENT EXARTICULATION AT THE HIP; COMPLETE RECOVERY.—Arthur E. Barker, F. R. C. S. Eng., Assistant Professor of Clinical Surgery, and Assistant Surgeon at the University Hospital, describes a case under this title, at great length. The patient was a riveter, aged twenty-nine, who fell from a roof and fractured his femur. The case illustrates, in the first place, what is, however, unfortunately rare in experience, namely, the possibility of recovery from pyæmia, even in a patient weakened by a most severe injury, prolonged suppuration, and an attack of erysipelas. Secondly, it illustrates the feasibility in some cases of amputating with the best results through the thigh for compound fracture, leaving a second compound fracture in the neighborhood of the hip joint to be treated otherwise later on, when the first amputation wound is healed. Thirdly, it shows that, in such a case, it is possible to exarticulate the whole of the remaining bone up to the hip joint, without re-amputation through the soft parts, but through a moderate opening in the outer side of the stump.—*British Medical Journal*.

A NEWSPAPER EPIDEMIC.—Last Monday's "*Tribune*" had a startling account of an alleged unusual prevalence of pneumonia in New York at the present time—almost amounting to an epidemic, it was suggested. We have seen no reason to believe that pneumonia is more rife now than it is liable to be at this time of the year. Diseases that show a maximum prevalence at a certain season, year after year, do not always reach their highest pitch at precisely the same time each year. Much depends on meteorological conditions, and something doubtless on circumstances that at present we are incapable of stating. This is true of pneumonia, as well as of other such diseases, and, granting the "*Tribune's*" statements, we see nothing in the facts to warrant its sensational manner of announcing them.

THE TEACHING OF PSYCHIATRY.—A committee of the National Association for the Protection of the Insane and the Prevention of Insan-

ity ask your attention to the need which medical students have of more instruction, didactic and clinical, in mental diseases. They say that, since the incipient stage of mental disease must always be passed under the observation of the general practitioner before the patient is finally committed to the expert as insane, it is extremely important that a knowledge of such diseases should be widely diffused throughout the profession. Usually the diagnosis of insanity is stated incorrectly or imperfectly in medical certificates; and a rational attempt to treat the patient at home is not made, because the physician shrinks from assuming a responsibility for which he has never been prepared. Medico-legal cases are often complicated and rendered obscure by the ignorance of the physicians who are called to testify in regard to them. Many cases of impending insanity are allowed to progress, when an adequate knowledge of the subject might have enabled the family physician to ward off the catastrophe. A training in psychiatry would, in the committee's opinion, fit the general practitioner for more successful treatment of mental symptoms in patients not actually insane. They believe that the time has come when in this country no course of medicine should be considered complete without attendance upon lectures and clinics on mental diseases; and that no student should be allowed to graduate without passing an examination in psychiatry. They therefore urge that such instruction be provided for in medical schools, by means of: 1. A chair of lectureship on psychiatry. 2. A clinic of psychiatry, held in an asylum for the insane. Both these forms of instruction, they add, have long been a part of the curriculum of the best European medical schools; and nearly a dozen medical schools in this country already advertise lectures on insanity as a part of their course.

THE AMERICAN JOURNAL OF OTOLGY.—The publishers of the "*American Journal of Otolgy*" announce the suspension of the publication of that journal until further notice.

ARMY INTELLIGENCE.—The Vancouver "*Independent*," chronicling the transfer of Assistant Surgeon C. L. Heizmann from the Department of the Columbia to the Department of the South, says: Many warm friends in Vancouver will miss Dr. Heizmann very much when he takes his departure. — Surgeon Page and Mrs. Page, and Surgeon Cowdrey and Mrs. Cowdrey were among the guests present at the recent marriage of Lieutenant Garrard, Fourth Artillery, to Miss Lane. Many other officers were present, not a few with their wives, and the affair is described as having been very brilliant. — The army medical examining board ordered to assemble in this city on the 1st inst will probably continue in session about three months.

NAVAL INTELLIGENCE.—Medical Director T. M. Potter and daughter Passed Assistant Surgeon S. H. Griffith, and Passed Assistant Surgeon Robert Whiting were registered at the Ebbitt House, Washington, during the week ending February 22, 1883. — Passed Assistant Surgeon S. H. Dickinson was one of the officers of the ill-fated *Ashuelot*. — The Kearsarge, which left Curacao for Saranilla, Cartagena, and Colon, February 8th, had Surgeon M. C. Drennan on board. — The "*Army and Navy Journal*" says: Passed Assistant Surgeon W. W. G. Willson is on trial for insubordination and willful neglect of duty. The specifications are, disrespect to his superior officer—the Surgeon of the Alaska—and refusal to give attention to a sick member of the crew. Medical Director A. L. Gihon and Medical Inspector E. S. Bogert are on the detail for the court. — Surgeon James A. Hawke has been ordered to the receiving-ship *Wabash*. — Passed Assistant Surgeon Howard E. Ames has been ordered to the receiving-ship *Colorado*. — Surgeon Thomas Hiland has been ordered to appear before a retiring board. — Surgeon John L. Neilson has been detached from the *Saratoga*, and placed on waiting orders. — Surgeon J. H. Clark has been detached from the receiving-ship *Wabash*, and placed on waiting orders. — Passed Assistant Surgeon Charles A. Siegfried has been detached from the receiving-ship *Colorado*, and ordered to the training ship *Saratoga*. — Passed Assistant Surgeon D. M. Gutieras has been relieved from special duty at Washington, and ordered to the *Swatara*, relieving Passed Assistant Surgeon W. W. G. Willson. — Assistant Surgeon William Martin has been granted leave of absence for six months from March 1st.

Lectures and Addresses.

ABSTRACT OF

THE CARTWRIGHT LECTURES

ON THE RELATIONS OF MICRO-ORGANISMS TO DISEASE.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

By WILLIAM T. BELFIELD, M. D.,

CHICAGO.

I LECTURE II.

SEPSIS AND ANTISEPTIC SURGERY.

THE speaker opened his remarks with the statement that the infectious diseases depending upon wounds, and, therefore, falling within the province of the surgeon, merited somewhat extended discussion. Such diseases were known to the earliest of the medical writers, and we might assume that they antedated man himself by so much time as the existence of highly organized life preceded him. He then reviewed the history of experimental researches upon the lower animals and the clinical history in man regarding the introduction of putrid animal matter, certain ferments, and inorganic substances into the system, and the effects produced thereby. The experiments of Panum had led him to the conclusion that the symptoms arising from the introduction of putrid substances into the system, symptoms of septicæmia, must be due to a definite compound which he called sepsin. The earlier experiments, and deductions drawn therefrom, of Hallier, Billroth, Klebs, Rindfleisch, Recklinghausen, Samuel, Pasteur, and others, were considered, especially with reference to the possible etiology of the symptoms of septicæmia which followed the subcutaneous injection of putrid substances, of the animal ferments, fibrin, pepsin, trypsin, etc., of inorganic substances, of liquids known to contain bacteria, and of those which had been treated in a manner to destroy organic life. The presence of bacteria in the tissues of animals or of man dead of septicæmia, as the sequel of gunshot wounds, etc., had been established by Rindfleisch, Klebs, and others, and it was generally concluded that the septic infection following the experiments alluded to might be produced either by organized or by unorganized substances; that the presence of bacteria was an epiphenomenon—a consequence, not a cause. Billroth was of the opinion, from much careful observation and experimental research, that the presence of bacteria was a result, and not a cause, of certain changes in the secretions and tissues, and he ascribed this result to the action of what he called a zymoid substance. It was possible, he admitted, that the presence of bacteria might aid the multiplication of this zymoid substance. Since the publication of his work, in 1874, Billroth had materially modified some of his views.

There soon appeared from various sources, especially from Koch and Pasteur, investigations from which deductions were to be drawn more or less incompatible with these views. Pasteur found that the tissue of an animal septically

infected contained microscopical organisms, the inoculation of which into a second animal caused a reproduction of the original disease. If, however, the organisms referred to were destroyed, abscesses might develop as before, but general infection would not take place. He therefore reached the conclusion that the presence of bacteria alone was responsible for the septic infection. It was to be remarked, however, that both Pasteur's deductions and the methods employed offered many vulnerable points. The method of culture in tubes and flasks had before been criticised.

Markedly different was the reception given a monograph published in 1878 by a young German physician, then almost unknown, Robert Koch, who made certain improvements in modes of investigation which had become absolute necessities for reliable original research in this field. Having demonstrated the life of the bacillus anthracis, which French physicians had for sixteen years failed to discover with the methods of their leader in this field of investigation, Pasteur, Koch turned his attention to the study of the etiology of certain infectious diseases. He injected from five to ten drops of putrid blood into a mouse, and death resulted within a few hours. No bacteria were discovered after death, and the blood and tissues of the animal were incapable of communicating the disease. He found, however, that the injection of a smaller quantity, one half to one drop, of the same putrid blood was followed by entirely different effects. In some cases the mouse was unaffected; in others transient fever ensued; in perhaps one third of the cases about twenty-four hours later there occurred progressive weakness, drowsiness, and, in from forty to sixty hours, death. The animal revealed no other pathological lesion than a local oedema at the seat of the inoculation, and enlargement of the spleen. Injection of the products of this local oedema into another mouse was followed by a like clinical history; and so on indefinitely. Here, then, was a result markedly different from that obtained after the injection of a larger quantity of the putrid fluid; a stage of incubation, local reaction, and a certain and uniform infectiousness. The blood evidently contained something which was not present in the blood of the first mouse experimented upon—something requiring time for the manifestation of its influence, and which finally distributed itself throughout the entire system. Such a mode of action implied reproduction, and reproduction was characteristic of organized matter. It was to be inferred, *a priori*, that the blood contained organisms, and Koch found that the blood, the serum, the white blood-corpuscles, etc., swarmed with bacteria. Since the blood of the infected mouse differed from that of the intoxicated mouse only in the presence of these bacteria, Koch ascribed the infectiousness to these organisms. Yet, although this association existed between the presence of the bacterium and the specific infection there still remained the objection that possibly the essential agent of infection was an unorganized substance contained in the material used for inoculation, and that bacteria were the result and not the cause; but it had subsequently been satisfactorily established by Koch, Gaffky, and Löffler that the bacteria alone would produce the result. Dr. Belfield quoted the results

of the investigations of several experimenters, going to show that the symptoms of septicæmia might be produced by other substances than those of putrefaction, such as the physiological ferments of pepsin and trypsin, hæmoglobin, etc., but whether the effect produced was due to the presence of bacteria or not, was immaterial to our present purpose. It would appear from the experiments of Schmidt, though the fact was not demonstrated in all cases, that the clinical and the anatomical features common to the various forms of septicæmia might be attributed to the rapid liberation of fibrin ferment in the blood, and that any agent, organized or unorganized, capable of producing such liberation, might induce the disease. This enabled us to understand many things otherwise perplexing.

The opinion that aseptic wound fever differed from sepsis in degree rather than in kind met with a serious objection in the fact that the former occurred within a few hours after the infliction of the wound, before decomposition and consequent sepsis could have occurred. The speaker mentioned facts connected with subcutaneous injuries which went to indicate that aseptic wound fever was caused by absorption of extravasated blood, especially as it had already been shown experimentally that blood might produce the same phenomena. Septicæmia was a collective name for processes more or less similar but etiologically distinct, at least in certain of the lower animals. Any one of several unorganized substances, any one of several bacteria, in the mouse certainly, might induce the characteristic symptoms. Clinical distinction was rarely possible.

The discussion of the subject of bacteria in connection with pyæmia began practically with relation to suppuration. Their presence in unopened abscesses had been demonstrated conclusively by Rindfleisch, Waldeyer, Ogston, Cheyne, and others. While the mere fact of association did not, of course, prove a causative relation, no other impartial and satisfactory hypothesis could be offered in the present state of our knowledge than that the micrococci caused this process; it was impossible to evade the conclusion that suppuration could be and was induced by micrococci. That it was produced by a particular variety of this organism seemed probable; that it was not induced by all species was evident, since micrococci were in various morbid processes in which suppuration did not occur.

Although our present knowledge of the etiology of septic infection was thus incomplete, our ability to prevent such infection was certainly more satisfactory. Cases of septic infection might be divided into two classes: first, those in which the possible source of infection was apparent, and, secondly, those in which such a source was not discoverable. The treatment of the former class, comprising wounds, etc., was based upon the assumption that bacteria entered into the morbid process. Thorough disinfection of the sponges, the hands, the knives and other instruments, etc., was a necessary measure against sepsis, some one of which details, however, was often overlooked by the surgeon. He had once seen a gentleman perform an operation which in itself was not dangerous, and it was maintained that Listerism had been observed, the instruments having been placed in a carbolic solution, the spray used, etc., but he neglected to

wash off the skin at the seat of the operation, and the woman died of purulent peritonitis.

Three factors were necessary to septic infection, viz.: first, the presence of animal tissue deprived of vitality, and hence capable of undergoing putrefaction; second, the presence of organisms capable of inducing infection; third, the presence of conditions permitting the vital activity of these organisms. The absence of any one of these conditions rendered putrid infection impossible, evidence in illustration of which could be obtained from outside sources, as in certain cases of extra-uterine pregnancy, in which air could not come in contact with the dead fetus, and in the experiments of Hiller upon himself in the introduction of bacteria into the circulation, etc. Practically, the surgeon had three methods for the prevention of sepsis from a wound; namely, exclusion of putrid material, or cleanliness, the exclusion of bacteria, and the application to the wound of substances in which bacteria were inert. The employment of these means constituted aseptic or antiseptic surgery.

There was a tendency on the part of surgeons to regard Listerism and antiseptic surgery as one and the same. It would be manifest, however, that antiseptic surgery was far more comprehensive than Listerism. Listerism meant, generally, but one of three possible ways of preventing sepsis: that was the exclusion of ferments. That this was not the only possible means of success was illustrated in the brilliant series of operations reported by Lawson Tait and Savory, who had observed the same method. But there still remained a considerable number of cases, notably wounds of the mucous membranes, in which the anatomical arrangements prevented the execution of either of these aseptic methods; bacteria could not be excluded, nor could perfect cleanliness of the wound be secured. In such cases asepsis could be theoretically obtained, however, simply by the presence of some substance in the wound which rendered vital activity of the bacteria impossible. A great variety of such agents had been employed, such as solutions of carbolic acid, corrosive sublimate, etc., but for these particular cases all such preparations, being volatile or soluble, were practically useless, and it was reluctantly admitted that operation wounds involving the mucous membranes could not generally be rendered aseptic with certainty. Between 1860 and 1880 Billroth performed the operation of extirpation of the tongue one hundred and nineteen times, and, notwithstanding the most careful attention, including the use of antiseptic solutions, twenty-six of the patients died—nearly all from septic infection. With the introduction of iodoform into surgery, a non-volatile substance, in the presence of which bacteria did not multiply, a long stride was taken in advance. Under the use of iodoform, wounds of the mucous membranes were as perfectly protected against sepsis as were wounds situated upon the external surface to which the Lister dressing had been applied. From 1880 to 1881 Billroth extirpated the tongue eighteen times, packing the wound with iodoform gauze, allowed to remain undisturbed from five to seven days; not a single septic infection occurred, and recovery took place in every instance. An operation which, though comparatively trivial, had, even in Billroth's skillful hands, been followed by a greater mortality

than that of ovariectomy, was now deprived of its septic terrors. Here was aseptic surgery *par excellence*, though the spray was absent; here was prevention of septic infection by measures which did not exclude bacteria from the wound, but simply restrained their development.

The method of Lister, conceived and devised from an hypothesis before the assumptions of that hypothesis had been verified, contained some errors of conception and execution. The spray, the sign manual of Listerism in the professional mind, seemed less essential since it had been learned that bacteria were less numerous in the atmosphere than had been formerly supposed. It was doubtful even whether the carbolic-acid spray had ever killed a single bacterium, for many of these organisms, as had been shown by the experiments of Koch, had a power of vitality in the presence of this fluid which was in some degree astonishing. It was probable, however, that, except in those cases of abdominal section where the spray caused positive injury, benefit might be derived from its use.

As applications to the wound, many substitutes had been proposed for the objectionable carbolic acid, some preferring corrosive sublimate, some iodoform, etc. In order to secure cleanliness, surgeons now generally appreciated the importance of ligating or twisting every vessel, however small, which could bleed. For the purpose of absorbing putrefying materials, Esmarch used turf dressing with great satisfaction; others used sand, with solution of corrosive sublimate poured into the wound. Perhaps one of the most important antiseptic measures was the insertion of deep sutures for the closure of the lips of deep wounds.

He repeated that antiseptic surgery was not, then, entirely comprised in the spray and carbolic acid; it was not simply a question as to the relative anti-bacterial properties of this and that so-called antiseptic agent. It was to prevent the entrance into and the formation within the wound of all substances, organized or unorganized, which went to interfere with nutrition. It implied the removal of all putrefying material, of blood, etc.; second, the exclusion of all ferments, bacterial or other; and, since neither one of these objects could be accomplished fully by the most perfect Lister or other dressing, third, the employment of substances in the presence of which bacteria were inert. The surgeon should avail himself of every possible means, without regard to special methods of this or that man, in order best to realize this object. Dr. Belfield remarked that it had been his fortune to see these conditions most nearly realized at Billroth's clinic, and with the best of results. He then gave a detailed description of the manner in which Professor Billroth was in the habit of dressing wounds at the present time.

He then considered three morbid conditions—erysipelas, diphtheria, and scarlatina—which, although exhibiting definite and distinctive clinical characteristics, were etiologically closely allied to pyæmia and septiciæmia. It was doubtful whether diphtheria had any etiological or anatomical right to distinction from pyæmia and septiciæmia, however definite the clinical distinction might be.

Original Communications.

ON THE CAUSATION OF MYOPIA.

By DAVID HUNT, M.D.,

Baltimore.

THE current hypothesis as to the causation of myopia assumes that it is in some way produced by near work, and that in some manner this result of near work is directly cumulated by heredity. There are differences of opinion as to the relative importance of near work and hereditary influences as causative agents, but there is a general agreement that the cause of myopia is included under these two headings.

We believe that this hypothesis is unsatisfactory. No case has ever been related where near work has apparently caused near sight—not even Professor Arlt's account of his own case—which can not be paralleled by reports of like or more marked cases in which it can be demonstrated that there has not been even an average amount of near work. On the other hand, as every practicing oculist knows, myopia is so frequently seen to arise in families where there is no trace of myopic ancestors, and the children of myopes are so frequently observed free from the disorder, that it is impossible to bring it under the laws which govern the transmission of acquired characteristics. Our space forbids going into details; but we think that this is unnecessary in this connection, since the insufficiency of our present hypothesis is demonstrated by our practice of helping out our notorious failure to demonstrate any cause included in near work, sufficient to affect the shape of the eye, by appealing to "hereditary predisposition," and, on the other hand, by supporting our claims as to the hereditary character of the affection, when exact observation contradicts them, by the same resource. In confirmation of these statements, consider, first, the recent statement of Pflüger: "Which, of all the injurious influences contained in continuous employment upon near objects is principally accountable for the development of myopia is now an unsolved problem"; and, second, the fact that Dr. Loring found only six per cent. of myopes, old enough to give intelligent answers to his questions, who had either parent myopic.

If there are doubts as to the truth of current theories, caused to a great extent by neglecting the natural history of myopia, and thus confusing concurrent phenomena with causative agencies, we can not remove those doubts, nor aid our search for the truth involved, by patching up a deficient knowledge of heredity with an unproved statement of the causative influence of near work. Perhaps no one name or authority exerts more influence upon the world in general in support of the prevailing hypothesis than that of Darwin. It is well to remember that he wrote upon this subject without giving the results of his own observations; with that candor which distinguished him, he applied to certain leading lights in the ophthalmological world, not for facts, but for ready-made judgments. These, according to his personal appearances, he accepted, and he went rather beyond his authorities in stating essentially that near vision produces

near sight, distant vision long sight, and that heredity directly cumulates these results. If Darwin had studied the subject himself, we have every reason to believe that, however important the pathological complications of myopia may render it to the physician, he would have been struck by the fact that in a general way errors of refraction increase together. Thus, among such short-sighted people as the Germans and the Italians, Mannhardt thought that one peculiarity might be found in the greater proportion of long sight in one race than in the other; no doubt either race demands and needs more and stronger convex glasses than do the inhabitants of the southern shores of the Mediterranean. Statistics of dealers in spectacle-lenses would be interesting upon this point.

Again, Darwin would not have omitted to consider that very prevalent, if less known, anomaly of refraction, astigmatism. He could not but regard this disease as an anomalous result of the exercise of a function like that of vision, and he would have found mixed forms of astigmatism—forms combining long and short-sighted meridians in the same eye, not to be explained as results of the function of the eye, and not resulting from a mixture of long and short sight among parents or ancestors.

Again, he would have found a difference in the refraction of the two eyes of very common occurrence,* and this difference, in spite of the theories of Schneller and others, he would have found it difficult to have explained in accordance with the prevailing hypothesis.

Again, he would have studied the question of heredity in those countries where myopia is now originating, and if he had found the ratio of myopic ancestors a smaller one than in older countries, where myopia has long been prevalent, he would probably have been very cautious about accepting an opinion as to the hereditary nature of the affection. On the other hand, if he found from the natural history of myopia that it developed in the field and in the school during the early years of life, he would have carefully refrained from ascribing to school-work as a cause an affection that merely occurs during school years. As far as the occurrence of myopia among adults is concerned, he might have felt the doubts which trouble many practitioners, who are aware how very little people know of their eyes, and how easily oculists even are deceived as to the slighter degrees of ametropia.

Again, the reports of observers like Macnamara would have shown him that among people making but little use of near vision, employed almost altogether in pursuits exercising distant vision, the rule is not hypermetropia, but emmetropia. Finally, considering the facts which practice daily affords in connection with those just mentioned, we think that this great investigator would have declared that the characteristic of the eye of civilized man is not, as appears upon superficial considerations, myopia, but variability (my-

opia, hypermetropia, and astigmatism). The characteristic of the eye of savage races, on the other hand, is fixity of type.

Before stating our own hypothesis of the causation of myopia, we beg the attention of the reader to a few general statements of anatomical relations in the young embryo. If we make a horizontal section of the head of a pig embryo one fourth of an inch long (Fig. 1), we shall find that the eye is composed essentially of a double walled cup. In its

FIG. 1.

cavity lies the lens (L), which at this period consists of a mass of epithelial cells, still connected with the epithelium of the surface, of which at a little earlier stage it formed a part. At the earlier stage referred to, the embryonic eye was globe-shaped, and the appearances now are as if the growth inward of the involution of epithelium forming the lens had pushed the anterior section of the former globe, or primary optic vesicle, in before it, as we may fold or push a section of a common rubber ball into a cavity, of which the remaining section forms the outer wall. After this involution of the lens, the double-walled cavity is called the secondary optic vesicle. Of the two layers, the inner (R') forms the retina proper, the outer (R°) and thinner layer, which was formerly of the same thickness as the inner, undergoes retrogressive metamorphosis, until it forms a simple layer of pigmented epithelium. This was formerly considered as a part of the choroid, but embryology has taught us that it really is a part of the retina. This outer layer of the retina is continuous with the layer of epithelium forming the walls of the hollow optic nerve, and is continuous by means of this structure with the epithelium forming the walls of the embryonic third ventricle (V°), the great cavity in the fore brain (FB) from the anterior portion of which the hemispheres (H) are developed. The cavity lettered V° is the fourth ventricle; fibers are seen running from its walls to the great Gasserian ganglion (G), which for some time during embryonic life is as large as the eye. All the embryonic connective tissue inclosing the portions of brain and the eye impresses one at this time as playing a decidedly passive part; while all the tissues of epiblastic

* Dr. Schneller (Graefe's "Archiv," Bd. xvi, Abth. 1) found, in 1,150 cases of myopia, the eyes alike in 455 cases; a greater degree of myopia on the right side in 416 cases; greater degree on left side, 279 cases. Dr. Schleich ("Mittheilungen aus der ophth. Klinik in Tübingen," drittes Heft.), in 578 cases of myopia, eyes alike in 243 cases; eyes unlike, 268 cases; cataracts in 11 cases, one-sided blindness in 56 cases.

or epithelial origin are actively shaping the brain, the organs of sense, and, in some way not yet fully made out, stimulating the production of such growths as that constituting the Gasserian ganglion. As far as I have observed, this ganglion originates independently in the connective tissue (head plates), but very soon fibrils can be seen connecting it with the brain, as shown in the cuts (Figs. 1 and 2).

In Fig. 2 is represented a section of the eye and surrounding tissues, from an embryo pig, seven sixteenths of

FIG. 2.

an inch long. The lens (L) is fully separated from the surface epithelium. The outer layer of the retina is now a simple layer of pigmented epithelium. In the anterior portion of this layer the cells are nearly cylindrical, and their outer portions are free from pigment. Behind the lens, between it and the inner layer of the retina, a collection of cells indicates the commencement of the formation of the hyaloid artery and connecting blood-vessels. This genesis of blood-vessels occurs in the embryonic vitreous. This structure is, I think, nothing more than the result of the retrogressive metamorphosis of embryonic connective tissue turned in to the optic vesicle behind the lens, and connecting with the same connective tissue at the anterior termination of the retina and through an opening on the under part of the eye vesicle. The opening referred to is caused by the folding in of the primary eye vesicle. We have described this process as in appearance the same as if the lens had pushed in before it the inner retinal layer; a more exact notion may be conveyed by supposing the primary optic vesicle to be turned in and pulled down over the lens, as a hood is pulled down on to the head. The neck opening of a hood would represent the fissure in the secondary optic vesicle. In early stages of development this fissure extends backward into hollow optic nerve, which is included with the eye vesicle in the process of folding down over the lens. Imperfect closure of the cleft causes coloboma of the choroid. It is probable that the point of entrance of the ophthalmic artery into the optic nerve marks the point at which this embryological fissure terminated posteriorly, since it is probable that the artery is a product

of the mesoblastic tissue included between the folds of optic vesicle and optic nerve, as they extended downward and forward to inclose the lens. Note that up to this time the structures which we have called the walls of the optic vesicle, optic nerve, and fore brain, are directly continuous, and exactly similar structures.

The Gasserian ganglion (G) is more clearly defined; the nerve fibers connecting it with the walls of the fourth ventricle (V') more evident; there is a change in the relative position of the eye and the ganglion; the eye seems to have approached, the ganglion to have receded from the surface.

No fact in the earlier history of the eye vesicle is more striking than that of its forming essentially a portion of the brain; its early history is much like that of the hemispheres, and it develops from the same structure but a little distance behind their point of origin. If we glance at their further development, we shall see that as the skull, the membranes, and the blood-vessels of the brain form in the layer of connective or mesoblastic tissue immediately surrounding it, so the sclera, choroid, and blood-vessels of the eye form in the same layer, enveloping the eye. It seems natural to suppose that as the brain tissue during its growth impresses a type upon the tissue containing it, which is afterward made permanent in the bony skull, so the brain tissue composing the eye impresses its type upon the tissue which is to form the sclera, and to conclude that this phenomenon of variability of the human eye, instead of being a direct variation produced by function and direct hereditary transmission, is a correlated variation, and that the brain is the organ with which the eye is correlated.

Fig. 3 is a section of both sides of the head of an embryo seven sixteenths of an inch long (Fig. 2 was traced

FIG. 3.

with prism attached to No. 2 eye-piece, Fig. 3 with prism and No. 1 eye-piece; $1\frac{1}{2}$ -inch objective was used in both cases). This outline figure is intended to furnish a comparative view of the connective and nerve tissues in this principal portion of the head at this stage of development; it can be readily seen to what extent a very slight increase of the brain (V', V'), eye, and Gasserian ganglion (G) may influence the connective tissue surrounding them, and so influence the shape of the skull, brain, membranes, and blood-vessels, sclerotic, choroid, and other structures of the orbit, all of which are soon to form from this very connective tissue.

Fig. 4 furnishes a glimpse of the processes which result in the demarkation of the sclera. The fibers (MN) seen on

FIG. 4.

each side of the eye are nerve and muscle fibers, and the connective tissue included between them and the eye is destined to produce the choroid, sclera, and a certain residuum, so to speak, of adipose connective tissue. At this stage it is the rule to find, upon sections from embryos hardened in Müller's fluid and alcohol, the layer of epithelium bounding the anterior surface of the lens separated from it, and adhering to the tissue which is to form the cornea (C); it is also the rule to find the two retinal layers adherent near their anterior termination—that is, at the site of formation of the ciliary body (C'). In the pig embryo at this stage (one and one sixteenth of an inch long) the lids have commenced forming (P). The well-developed curvature of the anterior portion of the eye, supported by the lens, contrasts strongly with the undeveloped, baggy posterior portion of the globe. The Gasserian ganglion (G), relatively smaller than in earlier stages of development, is in more intimate connection with the eye, and a bundle of nerve fibers nearly as large as the optic nerve (O) is seen proceeding toward the eye to mingle with the nascent muscular fibers; there is as yet no clearly defined sclera.

Every observer must have been struck with the difference between the growth and shape of the head of the human embryo from the fourth to the twelfth week, and the growth and shape of the head of any other mammalian embryo. Regarding this most obvious difference, I can not but think that Darwin's statement, that "variations do not commonly supervene at a very early period of embryonic growth," is a statement founded upon present knowledge, based upon means of observations too coarse to enable us to discover all the changes bound up in the tiny morsel which constitutes the young embryo, rather than a statement of the facts of the case. In this plain, well-marked difference between the head of the human and pig embryo, at corresponding stages of development, is it not probable that we have an early and material expression of the great difference between a free agent, working out his own progress, and an animal with dormant faculties, ruled by powers almost wholly extrinsic to his own organism?

But this difference existed in the blastodermic membranes, and, of course, potentially in the ova. Its result in man, particularly in civilized man, where all the functions of the nerve tissue, derived from the epiblast, have been greatly increased, must have been a certain disturbance in the relation of the embryonic layers. The equilibrium of the blastodermic membranes which we may suppose to have existed for ages is destroyed in the case of man by the conditions of his existence, and more disturbed as he progresses from the ancient caste civilization toward that type of western civilization which, while it has liberated the individual, has also loaded him with an ever-increasing burden of thought, care, and endeavor. The greater size of the cerebral hemispheres causing the greater frontal development of civilized man, the greater complexity of the cerebral convolutions, the greater difference between the weight of the hemispheres must represent a greater development of epiblastic tissue. It is difficult to suppose that such an increase, at east in the head, where the epiblastic and mesoblastic tissues are in such extensive and intimate relations (see Fig. 3), could have occurred without producing direct results, interfering in many ways with the usual course of transmission of hereditary effects, as we see these in the domesticated animals, where no such disturbance of the equilibrium of the blastodermic layers has occurred. Would not the action of this cause explain, to a certain extent at least, the fact that man alone, of all the animals which have undergone a great change from predominating distant to predominating near vision, has suffered such deleterious changes in the structure of the eye? In applying this hypothesis it is not necessary to demonstrate the co-existence of the largest eye and largest hemispheres; many conditions may influence the relation in a given individual. The fact that the hemispheres of the brain are of unequal size—and one observer at least has stated that the right hemisphere is the larger, and that this variation has resulted from causes connected with man's progress in civilization—is at least suggestive. How far the greater development of the convolutions in civilized man may be attended by an increase of cell growth in the young embryo, capable of affecting that part of the brain forming the eye of the young embryo, it is apparently impossible to determine. The supposition that it may have some influence is in accordance with physiological laws. Before leaving this subject, it may be observed that our hypothesis offers a rather more cheerful view of the future of the organ of vision than that now in vogue. An ultimate destruction of the eye of man must follow if this affection is caused by near vision, and directly inherited. Comparing the condition of the eye among the Germans with the condition of the same organ among the people of our own country, gives a rough measure of the increase which the Germans must expect, according to current theories, in the next few centuries, if these doctrines are true. If, as we suppose, this variation of the structure of the eye is correlated, it is obvious that the deformity will not exceed, to any great extent, the limitations which its dependence upon the changes in brain structure fixes. The bearing of this hypothesis upon the hygiene of the eye may also lead us to be a little more cautious in insisting too fiercely upon edu-

cational reforms from the ophthalmological stand-point. No doubt bad lighting, bad type, bad blackboards, etc., may aggravate lesions liable to affect the myopic eye, but it is more than doubtful if all these bad influences ever caused a case of myopia.

Staphyloma posticum is such a common attendant of myopia that any hypothesis pretending to account for the occurrence of the latter should throw some light upon the causation of the former. After reviewing the multifarious explanations of the causation of this lesion, including the latest, that of Dr. Paulsen, in the twenty-eighth volume of Graefe's "Archiv," I must confess that I have not yet received much light. Dr. Paulsen, for instance, supposes that the resistance which the sheath of the optic nerve offers to the movements of the globe causes this bulging of the sclera. I must confess that I can see no reason why the sheath of the nerve should not have given way in this struggle, rather than the sclera; but, if it is in accordance with physiology for such a result to follow such action, what blessed exception to physiological law preserves the ligaments of the great joints? What would be thought of an engineer who, attempting the solution of a problem embracing the action of all known forces, should confine his attention to purely mechanical powers, neglecting the consideration of all the great forces of Nature, as, for instance, electricity, light, and heat? Yet ophthalmological literature, particularly upon this subject of the causation of staphyloma, is full of mechanical treatises, comparable only to the lucubrations of the mathematical physiologists of the eighteenth century. Such theorizing is more dangerous as it is more ingenious.

Supposing the causes which have increased the parts of the fore brain, which we have hitherto considered, have also affected the Gasserian ganglion, we should also expect an enlargement of this structure. The history of this ganglion is so peculiar that an embryological increase of considerable importance might leave but the slightest traces in the developed individual. This ganglion has a relatively short period of increase in size, and this period is completed before the sclera is formed. As the different nerves and ganglia form, the embryonic Gasserian is broken up among them, and these fragments are soon incased in the cartilaginous skull, or shut into cavities, as the ciliary ganglion is inclosed in the orbit, where the conditions are such as prevent their future growth beyond the narrowest limits. According to the laws governing the increase of other ganglia, it is rational to suppose that the Gasserian is larger in the civilized man than in savages and domestic animals. Provided the increase takes place, it must, as Figs. 1, 2, and 3 make evident, encroach upon that portion of the connective tissue destined to form the choroid and sclera, and thus weaken these tissues in the part where the bulging or staphyloma occurs. In this process the degenerated epithelium of the outer retinal layer, united at this point to the developing choroid, might, and probably would, suffer changes affecting this membrane, while it is easy to see how the retina proper, for a long while an entirely independent and developing structure, might extend over that portion of the staphyloma characterized by the atrophy of the choroid and the weakness of the sclerotic.

Some additional confirmation of our hypothesis seems to me to be afforded by a study of the internal recti of the myopic and hypermetropic eye; these muscles in the former are long and weak, in the latter short and thick. It is commonly stated that the necessity of converging for the purpose of accommodation has caused this appearance in the muscles of long-sighted eyes. It is well known that myopes do not accommodate to any extent, and thus the difference is explained. Now, I do not see why an almost constant convergence, in the case of the myope, upon a point of vision lying near enough to bring this function of the internal recti into constant employment, should not cause as much hypertrophy of muscular tissue as convergence caused by an intent to aid the associated ciliary muscle in its action. On the supposition that an enlarged optic vesicle and enlarged Gasserian ganglion leave less mesoblastic tissue to be inclosed in the cartilaginous orbit, and that a consequent weakness should effect all the descendants of this mesoblastic tissue, and so give a type even to the appendages of the myopic eye, the causes of this weakness of the internal recti in myopic individuals are, it seems to me, more evident.

Whatever the truth or error involved in our theories may be, we beg indulgence for an attempt toward a scientific study of a certain aspect of the great question of heredity, which has received so much attention from so practical a surgeon as Sir James Paget. Who, that has practiced medicine and read his essays, has not felt the influence of the ignorance that blinds us in our attempt to solve some of the commonest problems connected with this subject. Embryology is the field upon which we must engage, to make the study of heredity a practical one; but embryology offers a more direct reward to the physician—it can furnish him with much aid in bringing scattered and disjointed facts and details of anatomy and physiology into a close and more logical union.

CASES ILLUSTRATING THE BENEFITS TO BE DERIVED FROM DIVISION OF STRICTURE OF THE RECTUM.

By CHARLES B. KELSEY, M. D.,

STURGEON TO ST. PAUL'S HOSPITAL FOR DISEASES OF THE RECTUM.

CASE I.—Mary P., aged thirty-five, widow, two children. The patient was sent to me for operation by Dr. Abbe, of New York. She had been under his treatment for various syphilitic manifestations for several years, and for at least five years, to his knowledge, had suffered from stricture of the rectum, which had been treated in various ways. At the time of the operation she was suffering from a constant discharge of blood and mucus from the anus, and never had an evacuation from the bowels without previously taking medicine, which she did twice a week regularly. Her general condition was fair, and there was not much pain when she used the laxatives and kept the bowels open. The ostium vaginae was much deteriorated by syphilis, and the growths, which had caused a good deal of hypertrophy of the labia. The urethra was ulcerated and partly destroyed, so that the little finger easily entered the bladder. The stricture began

about three quarters of an inch from the anus, extended higher than the index finger could reach through the vagina, and was so small that the finger could not be passed through it.

The whole mass of cicatricial tissue was divided in the median line posteriorly, the incision reaching several inches up the bowel and well above the disease, and including all of the perinæum between the anus and the tip of the coccyx, which was exposed in the wound. The hæmorrhage was free, and was controlled by packing the rectum with lint.

The patient did well in spite of adverse circumstances. The bowels moved for the first time on the seventh day after the operation. At the end of two weeks she was having comfortable, painless, well-formed passages without medicine, and with sufficient control of the sphincter for cleanliness. Four weeks after the operation, the patient was able to attend to her usual work, and expressed herself as perfectly satisfied with her condition, which was better in every way than for years before.

CASE II.—E. A. B. Patient operated upon in consultation with Dr. Rand, of Newark, N. J. The patient, a man, aged about thirty-eight years, had a distinct syphilitic history, and had suffered from stricture of the rectum for ten years, and from fistula for two years. For some months past he had noticed also a decided failure in sexual power, which he attributed to the rectal trouble. The fistula had once been cut without any relief, and the stricture had recently become so tight that he was afraid of its complete closure. To avoid this, he was in the habit of taking a very hard bougie, resting it upon the floor, and then, by sitting down upon the sharp end of it, forcing it into the bowel by the weight of his body. There was great trouble in securing evacuations from the bowels, and a constant muco-purulent discharge, with occasional escape of fæces involuntarily.

On examination, an exceedingly tight and firm stricture, which would allow of the passage of nothing larger than a lead-pencil, was found just within the external sphincter. The fistula was in the median line posteriorly, and was a trivial affair, having its internal opening just below the stricture, and being subcutaneous for its entire course. This was first divided, and then the stricture, which proved, after it had been cut sufficiently to admit the finger, to be nearly annular in form. The bowel was comparatively healthy above.

At the time of writing, just sixty days have elapsed since the operation, and the patient expresses himself as perfectly satisfied with the result. The wound is not quite healed, and there is, consequently, a slight discharge from the granulating surface. The passages are easy, painless, and natural, and there have been but two occasions when the fæces have escaped involuntarily, at both of which he was suffering from diarrhoea unconnected with the local trouble. He also has experienced marked benefit sexually.

There are many points which might be discussed with interest regarding these cases, and especially the one of ultimate result as regards recontraction after a series of years; but I am not as yet prepared to enter into them as I should like to do. I received a letter not long since from a lady upon whom I operated two years ago, which proved her to

be still very comfortable, and almost entirely free from annoyance; and I have other cases in which a longer interval has elapsed without recontraction to any marked extent. But my object in reporting these cases is to call attention once more to the marked and immediate relief which the operation affords, so that it may fairly be judged in comparison with any other method of treatment known to surgery.

"THE MADISON," 25 MADISON AVENUE.

A CASE OF MONSTROSITY.

By S. F. TAYLOR, M. D.,
LEAVENWORTH, KANSAS.

THE subject of the accompanying photographs was met with in the practice of Dr. H. B. Callahan, of this city. January 19, 1882.

The mother, aged twenty-six, German, was a multipara, healthy, and weighed one hundred and forty pounds. Ceased nursing her youngest child in August, 1881. In April or May, 1881, she aborted when supposed to be about seven weeks advanced.

Quickening, in the last pregnancy, was felt about November 20, 1881. Miscarriage threatened December 12, 1881, and subsequently; she had pain and flooding at intervals. January 18, 1882, she complained all day of severe pains, and next evening labor became fully established, with

FIG. 1.

the head in the first position. Delivery was easily and rapidly accomplished, the secundines following in due time; the placenta was healthy, the cord small, and pulsations strong. There was nothing peculiar as to the amniotic fluid.

The mother "did well," making a rapid and complete recovery.

The child survived forty minutes; weighed two pounds; and its total length was eleven and a half inches.

The head, thorax, and left upper extremity presented nothing abnormal. The right wrist was ankylosed in a semi-flexed position, and the thumb of that hand was represented by a supernumerary finger.

There was no osseous formation whatever to the pelvis.

The lower extremity was five inches and a half in length, and joined the trunk a little to the left of the mesial line. The entire member was flattened transversely, and reversed in its antero-posterior relations. The knee joint was slightly flexed and ankylosed, its flexure looking forward. The tibia and fibula were larger and heavier than usual, the former presenting the flattening in a marked degree. There was no apparent articulation at the ankle; the integument below this point presented the same appearance anteriorly

FIG. 2.

as did the plantar surface of the normal foot. The toes were represented by three rudimentary protuberances destitute of nails.

One of the most interesting features of the case was the complete absence of external formation whereby sex might be determined. The anus was imperforate.

The spine terminated in a slightly elevated protuberance about one inch and a half above the upper extremity of the femur.

I neglected to state that there was no specific history to either parent, no consanguinity.

Book Notices.

The Diseases of the Liver, with a Treatise on Jaundice; with the Special Applications of Physiology and Chemistry to their Diagnosis and Treatment. By GEORGE HARLEY, M.D., F.R.S., F.R.C.P., Physician to University College Hospital, London, etc. Illustrated by colored plates and wood engravings. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. 751. [Price, cloth, \$5; leather, \$6.]

This is a most attractive volume as regards binding and typography, and the very name of the author carries with it the promise of a scholarly, scientific work. From his special training we should expect him to give prominence to physiological chemistry, did he not emphatically state in the preface that such was his aim. "This treatise," he says, "has not been penned either for the use of the tyro or the dilettante in medicine, but for that of my qualified brethren." Further on he adds the rather discouraging opinion that the term "scientific physician" should be limited to those men only who, in addition to their regular medical education, have passed two or three years in the study of physiological chemistry.

Chapter II treats of the "Chemistry, Physics, and Physiology of the Liver," special attention being paid to the normal size and situation of the organ, with the possible errors arising during a physical examination. The functions of the liver are briefly described as four—viz.: 1, Sugar-manufacturing; 2, Fat-modifying; 3, Colorifying, and 4, Bile-forming.

In Chapter III, on the "Etiology of Jaundice," Dr. Harley contends earnestly for the theory of suppressed secretion, as opposed to Frerichs, Murchison, and Legg. His argument, however, is based upon a single case in which, though there was marked jaundice, the autopsy showed that the gall-bladder and ducts were filled with colorless mucus. It would seem as if more than one observation were necessary to settle such an important question.

Chapter V considers at length the "Treatment of Hepatic Diseases," and is written in a pleasant, colloquial style, which makes it very interesting reading. Not that there are any particularly new suggestions as to treatment, but old ideas are presented in an attractive form. Under the head of mercurials the author states that, besides the direct action of mercury upon the duodenum, whereby its stimulative effects are "communicated, by reflex nervous action, along the bile-duct to the gall-bladder, . . . exciting to immediate contraction its muscular coat," it acts in two other ways—through its antiphlogistic action upon the hepatic capillaries, and by impoverishing the blood "by its disintegrating power on the fibrin and its red corpuscles." Doubtless the latter theory will strike most readers (especially the *unscientific*) as rather fanciful. Since it rests merely upon the basis of the writer's assertion, we have no hesitation in criticising its appearance in a work which professes to give a solid foundation of scientific experiment and observation. The remarks on "colic remedies" are unsatisfactory, in that the author does not make clear what the relation is between the antiseptic powers of certain drugs and their value as hepatic remedies. Dr. Harley's experience with mineral springs will be read with interest, though with us they are less fashionable than in England.

With Chapter V we enter upon the concluding part of the work. There are seven pages on "Intoxications," which is described as acute, subacute, and chronic. The author stoutly maintains his allegiance to calomel as the remedy *par excellence*.

Chapters VII to XV, inclusive, treat of jaundice from the stand-point of its etiology, a novel but rather confusing arrange-

ment, since from the prominence given to one feature of a disease we are in danger of losing sight of other equally important symptoms. But this peculiarity is understood, if we bear in mind the fact that the book is avowedly a contribution to the chemistry rather than the pathological anatomy of hepatic diseases. We remark with some surprise the application of the term "Hepatitis" to congestion of the liver, in which Dr. Harley differs from standard writers on general medicine; and he does not justify such a use of the word by any reference to pathological observations. Under Chapter X, "Jaundice, the Result of Hepatic Disease, caused by Disease-germs," the author includes acute yellow atrophy, which he regards as a sporadic form of the so-called "contagious jaundice" of the tropics. The cerebral disturbances seen in febrile forms of hepatic diseases are explained by what is fitly termed a "novel theory"—that the germs present in the blood consume the oxygen necessary for the proper nutrition of the nerve tissue (!). This idea is further elaborated in the section on the "Etiology of Pyrexia," where it is stated that rise in temperature is "nothing else than the chemico-physical effects of the heat developed by the germ's respiratory activity." "These remarks may probably appear to some of my readers as absurd," adds Dr. Harley, apologetically, and he endeavors to strengthen his position by comparing the febrile phenomena to the ordinary processes of fermentation, in both cases diurnal variations of temperature being observed. "There is nothing surprising in the fact that the same periodic changes should equally take place in a living human body and in a dead wooden vat, etc." Further comment is unnecessary. We may be pardoned for delaying so long over this chapter, but we have done so because in it we touch the essence of the whole book—the effort of a specialist to reconstruct a new theory of disease from his own stand-point alone, a tendency at once harmful and to be deplored. A few pages further on, disease-germs are also made responsible for the fever observed in various diseases; in fact, it is only the *normal* odor (the author's italics) of the germs which we smell, and not that of the diseased tissues at all. This theory is advocated on grounds which seem to us quite as untenable as the preceding. Chapters XI, on "Biliary Concretions," and XVI, on "The Chemistry of the Excretions," are excellent, based as they are upon the author's wide knowledge of physiological chemistry.

With Chapter XVII we enter upon a consideration of "Diseases of the Liver not necessarily associated with Jaundice," under which are included abscess, carcinoma, hydatids, cysts, and syphilitic, fibroid, fatty, and amyloid forms of degeneration.

We can only speak briefly of the remainder of the volume. The chapter on "Abscess" presents a thorough and comprehensive view of that subject. Under the section on "Cancer" the statement is made that "the existence of a veritable specific form of cancer-cell is not a conceit of the imagination, but it is easily and infallibly recognizable by the eye of the initiated." This is only another example of the dogmatic assertions in which the book abounds. Nearly fifty pages are devoted to the subject of "Hydatid Disease of the Liver," while amyloid degeneration is dismissed with three. Chapter XXVI deals with "Affections of the Gall-bladder and Common Bile-duct." A concluding chapter treats of hints in diagnosis, and briefly sums up the entire subject.

We cannot conclude without a few words as to the general impression of this book. Notwithstanding the acknowledged learning and ability of the author, the high scientific standard at which he aims, and his clear and forcible style, a certain feeling of disappointment steals over us as we turn the last page and ask whether we have indeed unraveled "the tangled skein of secrets which involves the vast majority of hepatic disor-

ders," a task in which Dr. Harley promised to assist us, through the aid of physiological chemistry—"the only talisman." It is not for the general reader to pass too severe a judgment upon a monograph which represents the results of years of study and observation. Such a work rests upon its own intrinsic merits, not upon the varying opinions of individual critics. The book at which we have glanced so hastily is thoughtful, suggestive; we leave it to the judgment of others whether it adds to the sum of medical lore, whether the intricate phenomena of disease are explicable by the light of any single science.

The Diseases of the Spinal Cord. By BYRON BRAMWELL, M. D., F. R. C. P. (Edin.), Lecturer on the Principles and Practice of Medicine, and on Medical Diagnosis, in the Extra-Academical School of Medicine, Edinburgh, etc. Edinburgh: MacLachlan & Stewart, 1882. Pp. xxiii-300.

For the student of neurology, and, as well, for the practitioner who has not yet reached an "expert" eminence from which he can look down upon all text-books, Dr. Bramwell's present treatise is, beyond comparison, the best work of its kind which has thus far come to our notice. Beginning with the anatomy and physiology of the cord, the reader is gradually led to foresee the symptomatology of lesions of different tracts, and, if he possess ordinary intelligence, will find himself a tolerable diagnostician even before he reaches the specific descriptions of classified spinal diseases.

A prominent feature of the author's teaching lies in considering the spinal cord as a series of segments, each of which, with its anterior and posterior pairs of nerve-roots, may be viewed as "a distinct spinal cord for a definite area of the body." The relations of these segments to each other and the functions of their several parts are described in accordance with the most recent state of our knowledge, and ingeniously demonstrated by means of diagrams, in the use of which Dr. Bramwell is peculiarly happy. As regards questions still in dispute among physiologists, the opposing views of different authorities are in most instances simply stated without any indication of the author's preference, although he appears to look with favor on the theory that the lateral columns convey some portion of the sensory tract, and distinctly affirms the almost total decussation of the sensory fibers at or near the level of their entrance to the cord. Of the relative parts played by the posterior gray or white substance he says nothing definite, but leaves us to infer that he regards the latter as the principal conducting channel to the cerebral perceptive center, through the posterior part of the internal capsule. Of the rather visionary subdivision into special tracts for touch, pain, tickling, heat, etc., he says (wisely, as it seems to us) nothing at all. Vaso-constrictor and vasodilator fibers are "probably" located in some as yet undetected part of the lateral columns, with re-enforcing vaso-motor centers in the cord itself.

The next section treats of the alterations of functions attending pathological conditions of the various portions of the cord. Intra-medullary lesions are studied as they are limited to definite physiological tracts, or affect, indiscriminately, a greater or less extent of the transverse section, and under the former head the distinction between primary disease and secondary degeneration is lucidly explained. The pathology and symptomatology of lesions involving, respectively, the anterior cornua, the crossed pyramidal tracts, and the postero-external columns, are successively considered; then those of "indiscriminate" lesions, comprising myelitis, disseminated sclerosis, intra-medullary hemorrhage, and tumors; and, finally, of the conditions arising from extra-medullary lesions of the meninges or osseous structures, hemorrhages, or tumors. Throughout this

NEW YORK, SATURDAY, MARCH 10, 1883.

THE NAVAL MEDICAL SOCIETY.

IN a recent number of the journal our Washington correspondent alluded briefly to the newly organized Naval Medical Society. The society holds monthly meetings, and, judging from the first number of its "Proceedings," a copy of which has kindly been sent us, as well as from numerous other signs that have been given by the medical corps of the navy during the past few years that it has no intention of confining itself wholly to the routine work of the service, the organization is destined to become one of no little importance. In a circular accompanying the number of the "Proceedings" to which we refer, we find it stated that "the officers of the medical corps of the United States Navy, in order to establish more intimate social and friendly relations among its members, to furnish occasions for the interchange of professional experiences, and to assist each other in scientific inquiry and research, have agreed to form an association, to be entitled the Naval Medical Society, in which every officer of the medical corps shall have the right of membership upon notifying the secretary that such is his desire."

At the annual meeting, held January 4, 1883, the following officers were elected for the current year: President, Dr. Albert L. Gibon; Vice-President, Dr. John M. Browne; Secretary, Dr. James M. Flint; Business Committee, Dr. Thomas J. Turner, Dr. Adolph A. Hoehling, and Dr. Thomas H. Streets. The Business Committee is charged with the business affairs of the society, such as the appointment of places of meeting, unusual correspondence, the selection of subjects for presentation to the society, the arrangement of public lectures and publications when they may be considered advisable, and the suggestion of provisions for defraying incidental expenses that may be thought expedient. All these matters are generally much better managed by a committee than by the entire body for which they are working, and with a very decided saving of time to the latter. We think, therefore, that the new society has done an exceedingly good thing in turning over its business affairs to a committee at the outset. Many a snarl will thus be prevented, and the society will be able to give its whole attention to its legitimate work.

The contents of the first number of the "Proceedings" embrace four papers upon various aspects of "The Line of Duty," or, more definitely stated for the civilian comprehension, a consideration of the circumstances which should incline a medical officer to report that a certain death, injury, or disability was met with as the result, to a greater or lesser degree, of exposure "in the line of duty," or, contrariwise, that it was not so incurred, with a view to support or invalidate a claim of pen-

sion. It will be seen at once that no more practical subject, or one more intimately connected with a just and intelligent performance of one of the weightiest tasks that can be imposed on a medical officer, could have been presented for discussion. That the members of the society entered earnestly upon its consideration is evinced by the industry displayed by the authors of the papers, Dr. J. M. Flint (two papers), Dr. T. D. Myers, and Dr. T. J. Turner, in citing instances, real and hypothetical, in applying precedents, and in analyzing both the one and the other, as well as in shedding the light of medical knowledge on the matter. It is still further evinced by the fact that the discussion occupied the society for three consecutive meetings, ending in the adoption of the following resolution:

"Resolved, That it is the sense of the Naval Medical Society that a man or officer who is receiving pay, and is subject to orders, and who becomes disabled by disease or injury during his military career, should be considered as incurring his disability in the line of duty; the disease or injury not being the result of any act of personal imprudence or impropriety, or existing prior to his entrance into the service, or the consequence of inherited disease."

It seems to us that the positions taken in this resolution are sound beyond cavil, and that their deliberate expression as the outcome of so prolonged and earnest a debate by such a body should go far toward systematizing rules of practice in the matter of granting or withholding pensions. There is one point that seems to us specially noteworthy: it is assumed that the disqualifying circumstances alluded to in the concluding part of the resolution are enough, by their mere existence, notwithstanding they were not detected at the medical examination of the cadet or the recruit, to invalidate an application for a pension. "The Government," said Dr. Flint, "does not hold itself responsible for the errors of judgment of its examining surgeons, and does not take the recruit as it would buy a horse, accepting the consequences of any defects undiscovered at the time of purchase. The recruit warrants himself to be sound." Such a position as this, enunciated not in any spirit of opposition to just claims, but as a succinct and forcible exposition of numerous decisions, and, we may add, embodying the conclusion to which an unbiased mind must come, ought to have some effect in preventing the disappointment that so often follows in the train of false hopes on the part of claimants—hopes fed by viewing the cause of disability only through a medium warped by self-interest. An analogous case is that of the claimant of life insurance, in an instance in which the insured, affected with disease potentially, but with no overt manifestation, thinks it no harm to conceal the fact, so long as the medical examiner fails to detect it, and puts no direct questions bearing upon it. There are many men, essentially honest men, too, who take this view of an application for life insurance: that the company tacitly undertakes to abide by the consequences of any failure on the part of the examiner to bring out the whole of the facts bearing upon the applicant's expectation of life. They forget that they are really understood to *warrant themselves to be*

sound, and that the medical examiner is not pitted against them in a trial of skill as to which of the two shall outwit the other, but rather is charged with the duty of bringing his special knowledge to bear in the detection of hidden signs of present or impending failure of health.

It is by no means a foregone conclusion that every insured man who dies leaves a valid claim against the company, or that every officer or enlisted man killed or disabled while in the pay of the Government furnishes just occasion for a claim to pension. And yet, while the Naval Medical Society has thus given in its adhesion to naked justice, we can well believe the full truthfulness of Dr. Flint's concluding sentence: "No medical officer ever wrote 'not in the line of duty' in a case involving the reputation or comfort of patient or family without a clear conviction of duty and the keenest sense of regret; and honor, and not obloquy, is due the man who, with the courage of his convictions, resolutely performs a disagreeable duty which offers him no possibility of reward except that which flows from his own consciousness of rectitude."

THE NEW YORK MILK SUPPLY.

THE well-to-do New Yorker who, when he has entered upon that rural tour of inspection which he is called upon to undertake every spring, in the hope of securing a tolerable retreat for his family during the hot months, listens, without any display of impatience, to the thrifty farmer's boast that "city folks" rarely get a taste of such milk as he proposes to furnish his summer patrons with, can do so quite complacently, for he knows that every morning milk is brought to his door that the ordinary farmer would look upon as too good to be used in his own family without dilution, or *a fortiori* to be set before those who, he takes it for granted, really know no more about the quality of milk than he himself knows or cares about the consequences that may follow the contamination of well-water.

The city man knows that the milk he gets at home is far superior to what his family are at all likely to be provided with by the keeper of a country boarding-house, and he knows, too, that in his own house his children have all they want of it, which, to judge from their past experience, is not sure to be the case during their sojourn in the country. In short, he knows that he has abundant reason to be satisfied with the milk supplied to his own household, but as to the liquid called milk that the poor are able to obtain for their children in the city, if he ever thinks of the matter at all, he is apt to place a blind trust in the supervision of the Board of Health—a supervision that, we really believe, does indeed go far to protect the poor children of the tenement-house districts against the vile stuff that was formerly dealt out to them from the so-called "dépôts."

We can well understand the warfare waged by the milkmen against the lactometer. That little device, together with the other measures employed by the watchful inspectors, tends most decidedly to restrict the rapacity of the middlemen to the two-hundred-per-cent. advance, more or less, on the producer's price; and to do away with the time-honored side-profits of

skimming and the free use of the pump. The Board of Health has full power to stop the sale of skimmed milk, and we understand that it exercises that power. Whatever may be thought of the absolute right of the Government thus to interfere with the sale of an article not in itself directly noxious, but only indirectly injurious, this is certainly a case in which it would be difficult to devise any means of preventing unscrupulous retailers from adding to skimmed milk just enough fresh milk to bring it up to the standard of the milk given by the poorest of cows, to use the words of one of the daily papers, except the positive prohibition of the sale of skimmed milk. Moreover, the prohibition need work no hardship to any one, for whoever really needs skimmed milk for any particular purpose has only to skim his own milk, and, if he can not make use of the cream himself, he will find a ready market for it.

But, as we understand it, the power of the Board of Health is restricted to the city; it is still open to middlemen to manipulate milk *in transitu*. We trust, therefore, that even this resource of knavery will be cut off by the operations of an organization that has been started, seemingly under unusually favorable auspices, with the avowed purpose of driving dishonest dealers from the field. This organization, known as the Erie Milk Producers' Association, with its headquarters at Goshen, has obtained the promise of most substantial co-operation on the part of the officials of the New York, Lake Erie, and Western Railroad, who undertake (1) to make an arrangement with other railroads whereby each will return all "foreign" cans to the proper road; (2) to detail an official to collect detained cans belonging to its patrons, and return them to their owners; (3) to provide free passage and every facility for a milk inspector on every milk train; (4) to sell the surplus milk at not less than the established price, and return the cans at once, remitting the money to the farmer; (5) to return such milk as can not be sold, free of charge; (6) to collect the bills for milk with the freight when requested, and remit to the farmer without charge or commission.

Another very promising feature of the scheme is, that two of the traveling inspectors appointed by the Board of Health of the city have received the same appointment from the State Board of Health and from the Milk Inspector of New Jersey, so that there can be no question as to their jurisdiction at any point on the route between the milk-producing counties and the city. The association undertakes, also, to furnish milk to customers at a reasonable profit to the producers, doing away with the extortion of the middlemen, which latter have heretofore, in plain violation of the common law, established both the price paid to the producers and that demanded of consumers. In view of the leading part played by the railroad in question in the business of bringing milk to New York, and in view of the fact that the movement does not put on the sentimental cloak of philanthropy, but is nothing more nor less than a business-like and straightforward effort on the part of the milk-producers to better their own condition by a system which, if carried out according to their promises, will certainly not only have that effect, but also benefit the community at the same

time—in view of these considerations, it seems to us that a great deal may be hoped for from the organization in the direction of insuring the provision of pure milk for the entire population of New York.

THE SKIN AND CANCER HOSPITAL.

NOTWITHSTANDING the great number of hospitals with which New York is supplied, both general and special, we doubt if there are many practitioners here who have not at times had occasion to regret the practical non-existence of any institution to which patients with certain forms of cancer, especially those unable to obtain the private services of a competent surgeon and a capable nurse, to say nothing of proper quarters, could be sent with a reasonable expectation that they would receive the full benefit of what hospital treatment should be able to accomplish for them. We do not mean to imply by any means that there are no hospitals in New York into which, from the nature of the case, it would be hopeless to attempt to get any cancerous patient admitted, for, strictly speaking, such is not the fact. In individual instances, however, the circumstances often amount to such a state of things. Take, for instance, the case of a woman with cancer of the uterus. The doors of the Woman's Hospital are closed against her, unless the disease happens to be so equivocally manifested as to make a positive diagnosis at the outset impracticable. She is very likely to find that those in charge of the general hospitals feel constrained to deny her admission, in order that they may keep what few spare beds they may chance to have, if any, for the benefit of sufferers for whom, it is very properly felt, surgery has a better prospect of accomplishing something tangible. Even those general hospitals that are provided with a special gynecological service find it necessary to limit the number of patients that they can admit into that department. And so the victim of uterine cancer often finds herself effectually debarred from any better resort than an almshouse, a home for incurables, or her own wretched abode, her continued residence in which not only subjects her family to an amount of suffering scarcely less than her own, but actually shortens her life, and deprives her of the palliation she would be pretty sure to obtain in a hospital.

The need of a special hospital for the treatment of cutaneous diseases, while probably not so obvious, is one that had really come to be quite pressing. In the present state of dermatological practice, topical measures play such an important part, and their systematic application is so indispensable to the full degree of success attainable, that surely no one at all conversant with this branch of medicine will question the great advantage of having provision made for the satisfactory employment of all the appliances that belong to hospital treatment in the case of patients with cutaneous affections. To those who have not had their attention turned to the importance of taking measures for curing such patients with all possible celerity we would suggest that many skin diseases are contagious, and that every victim of one of those affections may serve to spread the disease through the community. Let

any one reflect that it is quite within the power of such a hospital as this to cure a man of the itch within a few hours, and send him home shorn of his capability of imparting that disease to others. With very little qualification, the same may be said with regard to several others of the dermatoses, some of which, if allowed to run on unchecked, lead to permanent disfigurement if to no graver evil.

In view of these considerations, it is our conviction that there will be no lack of work, even at the outset, for the New York Skin and Cancer Hospital, which has recently been established. A temporary building, at No. 243 East Thirty-fourth Street, has been fitted up for the purposes of the hospital, and the trustees describe the building as suitable, although they realize that its capacity is not all that is needed. On this account they have already selected land elsewhere for a permanent and larger building in the future. In behalf of no similar undertaking could the aid of the benevolent be asked with more propriety, or, we will add, be claimed more justly.

THE ILLINOIS STATE BOARD OF HEALTH.

IN our issue of January 20th, speaking of the regulations adopted by the Illinois State Board of Health with regard to the "good standing" of medical colleges, we said: "Indeed, in the list of institutions approved of by the board we find several which do not require of candidates for graduation all the conditions that the committee enumerate." We are glad to learn that after the sessions of 1882-'83 the diploma of no college will be recognized which does not conform to all these requirements. This action of the board strikes us as the most decided step yet taken in this country to compel the adequate education of medical men, being of the same effect, in kind if not in degree, as the State examination in Germany. It will be noted that several of our leading colleges will have to raise the standard of their curriculum, or else their future graduates will be debarred from practicing in Illinois on the strength of their diplomas.

THE PHYSICIANS' MUTUAL AID ASSOCIATION.

MORE than once before we have taken occasion to commend the excellent work that has been accomplished, year after year, by the New York Physicians' Mutual Aid Association, and it is with great pleasure that we see, by its last annual report, that the field of its beneficent operation is still growing larger, while the benefit to each individual likewise increases.

Financial success is the final test of any undertaking of this sort, and, judged by that standard, the association may certainly be said to stand now on an assured footing. The accounts of the association, as many of our readers are doubtless aware, deal with an assessment fund, a contingent fund, and a permanent fund. Each of the three is shown by the report to have increased during the fiscal year—the first from \$455.67 to \$640.87, the second from \$226.68 to \$240.26, and the third from \$8,858.76 to \$10,586.38. The increase in the permanent fund is an achievement on which the association is specially to be congratulated, for, now that it has reached the amount specified by the by-laws as that under which its proceeds can not be touched, it can be made available for certain measures of relief that heretofore have been impracticable. For this favorable state of things the association, not only as it stands now, but in the growing membership that we trust is before it, is indebted to the generosity of a few of its members, and their example should make it easier hereafter for the association to extend its

resources by greater increments than are provided for by the way in which the fund is constituted. It is our earnest hope that such may prove to be the case.

THE ELECTRICAL TREATMENT OF EXTRA-UTERINE PREGNANCY.

WE recently commented upon a paper by Dr. A. D. Rockwell, on "The Successful Treatment of Extra-uterine Pregnancy." We would now call attention again to that one of the author's seven cases which was one of associated intra-uterine and extra-uterine gestation. This, it would seem, is an exceedingly rare complication, for, according to Dr. B. B. Browne, of Baltimore, whose researches into the literature of the subject appeared in the last issue of the "Gynecological Transactions," but twenty-four reported cases could be found. In one of these cases, the extra-uterine fetus passed down upon the posterior fornix, and was removed through the vagina. This was followed by the birth of the intra-uterine child alive and the recovery of the mother. In three other cases laparotomy was performed, with fatal results to the mother, in all. Of the twenty remaining patients who were left to nature, eleven died, while nine recovered by the discharge of the fetal remains through the process of ulceration. But, of the whole number, the child survived in seven cases.

In the light of Dr. Rockwell's report of the efficacy of electricity in extra-uterine pregnancy, and especially in his case of twin pregnancy, the statistics are of much interest, for if by this agent the fetal life can be so readily destroyed without injury to the mother, and, in cases of twin pregnancy, without disturbing the intra-uterine gestation, the use of the method constitutes an era in the management of these cases.

Proceedings of Societies.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held December 20, 1882, Dr. CHARLES C. LEE, President, in the chair.

The pathologist read the following REPORT ON THE UTERUS EXTERPATED BY Dr. W. C. BURKE, of South Norwalk, Connecticut, presented to the Obstetrical Society, December 5, 1882. The specimen was preserved in Wickersheimer's solution, and, therefore, probably somewhat increased in size. The uterus measures, from os to fundus, external measure, 75 mm.; from tube to tube, 40 mm.; in circumference just below the tubes, 95 mm.; around middle of cervix, 100 mm. The depth of the cavity of the uterus is 65 mm., of the body 25 mm., the isthmus 5 mm., and the cervix 35 mm. The wall of the body and of the cervix measure each 15 mm. in thickness. All these measures are normal except that of the cervix, which is increased 10 mm. in length.

The mucous membrane of the body and isthmus looks healthy. Of that of the cervix, on the contrary, a narrow longitudinal strip only on the posterior wall has a healthy appearance, and shows plicæ palmatæ, all the rest being transformed to a partially bushy, partially pulpy mass, at the upper end of which, on the anterior wall, is seen a polypoid growth of the size of a hazel-nut. The os externum looks healthy, but is distended by the diseased mass situated immediately above it, and showing in its opening.

Part of the cervix was hardened in a concentrated solution of picric acid, and sections thereof stained with ammoniated carmine.

The Inner Half.—Near the inner surface the tissue is composed of very small round cells, with very little connective tissue between. The cells have a comparatively large nucleus. Very large and thick-walled arteries are seen in this part. In many places the cells are found in rows like beads on a string, which probably is due to the degeneration of muscular bundles to sarcomatous tissue. Glands are nowhere seen.

On the villi covering the inner surface are found numerous large ciliated columnar epithelial cells with nucleus, but even on excellent specimens they nowhere form a regular brim, as on the healthy cervix.

In the remoter parts is found muscular tissue, but with a great increase of connective tissue, in which are interspersed isolated cells similar to those near the internal surface.

Outer Half.—This is formed by normal muscular tissue, but the bundles are separated by broad bands of connective tissue interspersed with single spindle cells, which seem to be muscular fibers, but may also be connective-tissue corpuscles.

The diagnosis is, therefore, *Diffuse Small-Round-Cell Sarcoma* starting from the mucous membrane of the cervix, extending outward, and chronic inflammation of the outer half of the cervix.

It is very rare that sarcoma, especially the diffuse form, starts from the cervix. Generally the process begins in the submucous muscular tissue of the body of the uterus. (Gusserow, "Neubildungen des Uterus," p. 150, in Billroth's "Frauenkrankheiten," vol. i.)

TUBERCULOSIS IN CHILDREN.—Dr. B. I. DAWSON, presented the lungs, the spleen, and a portion of the left side of the diaphragm, removed from an infant that had died in the Foundling Asylum of general miliary tuberculosis. The specimens were thickly studded with tubercles. The interest of the case related largely to the difficulty of diagnosis, which, as Dr. Dawson believed, was usual in these little patients. Although tuberculosis had been suspected, it was not positively diagnosed before death.

MEINGITIS IN CHILDREN.—Dr. DAWSON also presented the brain and portions of the spinal cord of a boy five years of age who died recently in the Foundling Asylum of cerebro-spinal meningitis arising from pyemic blood poisoning. The history, in brief, was as follows: The child some months ago had been sent out of the asylum to be cared for, and was returned about two days ago, simply with the history that it was not strong, and had vomited occasionally. There was severe eczema of the scalp, with the formation of numerous abscesses. The temperature was 100-25° Fahr. The abscesses were opened, poultices were applied, and tonic treatment was prescribed. On the third day, however, the temperature had risen, pus was being discharged from the abscesses, the child was peevish, and its general appearance was not favorable. Although it relished food, and nausea and vomiting were no longer present, there was some trace of albumin in the urine. The child appeared better on the morning of the 11th of December; the temperature was 101° Fahr., but by evening it had risen to 103-75°. The fever diminished toward morning, and there was marked perspiration. The general treatment was continued, with the addition of quinine and salicylates. Dr. Dawson was of the opinion that the impression that the elevation of the temperature was due to pyemic poisoning originating in the abscesses, as they were ill-looking, and the scalp was very sore. On the 14th of December, however, he observed that the child was not better. The temperature was 103-75°, twitching of the left arm, the temperature was 103-75°, sores began to collect on the teeth, the child vomited twice in the evening, and death took place on the 15th, about twenty minutes after having a convulsion.

The autopsy was made by Dr. NEUMANN, pathologist to the

asylum. The body was well nourished, the skin was very pale and faintly livid in spots. The condition of the scalp was as had been mentioned in the history. A recent thrombus was found in the mesial sinus, and one evidently of older date in the left lateral sinus. The surface of the brain was covered with pus; the general color was a dull yellow. Over the side of the left hemisphere was found an extravasation of blood, which was disorganized, dark and granular in appearance; the ruptured vessel was shown to be a branch of the middle cerebral artery. The convex surface of the right hemisphere showed signs of inflammation, as did also that of the left, but in slighter degree. The exudation on the base was less than on the convexity. The lungs were oedematous, the pleural cavity contained about one ounce of turbid fluid, the heart was normal, the liver was fatty and enlarged, the spleen was normal; one kidney appeared to be affected with parenchymatous inflammation, which, however, had not been evident from an examination of the urine during life. The spinal cord showed a purulent exudation on its posterior surface.

The specimens were interesting as showing that meningeal inflammation must have existed for a much longer time and in a much severer degree than had been supposed, and the case was an illustration of what had been remarked by others—that children show the effects of these acute inflammatory affections in a less degree than adults. The pathologist had confirmed Dr. Dawson's opinion that the meningeal inflammation arose from pyæmic blood poisoning due to the abscesses resulting from the eczema of the scalp.

With regard to the first case, Dr. Dawson asked Dr. W. M. Polk if he had found it difficult to make the diagnosis of miliary tuberculosis in children from the physical signs.

Dr. Polk replied that he had found it very difficult to do so. The physical signs were very much like those of simple capillary bronchitis, and where these were present, in connection with signs of tuberculosis in other parts of the body, he should suspect pulmonary miliary tuberculosis.

PLACENTA FROM A CASE OF TRIPLE PREGNANCY.—The specimen was presented by Dr. Polk, and had been removed from a woman who miscarried at about the eighth month. On account of the large size of the abdomen, Dr. Polk had suspected a twin pregnancy, and, therefore, made careful examination for the beat of the fetal hearts, but he was unable to distinguish more than one sound, which, however, was rather widely diffused. Labor was very easy indeed, and continued only an hour and three quarters to the expulsion of the placenta. But a few minutes elapsed from the birth of one child to that of the other in succession. All lived, were females, and weighed about five pounds each. The placenta weighed forty-six ounces, and showed very plainly three sacs, one of them being quite distinct from the two others. Dr. Polk thought the fact of there being no apparent demarkation in the placenta went to show that the ova had proceeded from the same ovary, although he must admit, with Dr. Garrigues, that this opinion was not susceptible of positive demonstration. The close proximity of two of the cords, their insertions being side by side, would also seem to point to the probability that two of the fetuses had sprung from a single ovule with a double germ.

Dr. H. J. GARRIGUES remarked with reference to the commonly accepted view as mentioned by Dr. Polk—namely, that delivery was likely to take place at a time corresponding to a menstrual period—that, according to his observation, the statement was not sustained by facts. He had observed that usually both ovaries were not congested at the same menstrual period, but that they were congested alternately, and, in the cases of which he had been able to keep a record, delivery, whether premature or at full term, had by no means always occurred at a

time corresponding to some even multiple of the time between the beginnings of two menstrual periods. According to statistics given by Matthews Duncan of cases where the exact date of conception was known, confinement took place more frequently on the 275th day than on the 280th.

Dr. F. P. FOSTER remarked that it was not unusual for menstruation to occur at intervals a few days longer or shorter than a lunar month, and should the ideal period be anticipated by but half a day for ten months in succession, labor would fall upon the 275th day. Dr. Foster also remarked that about seven years ago he attended a patient who gave birth to triplets, all of the circumstances corresponding almost exactly with those in the case just related by Dr. Polk. Labor was short and easy. The children, all of whom were females, were born in rapid succession; the placenta was a perfect counterpart of what had just been exhibited.

Dr. CHAMBERLAIN attended a patient many years ago who miscarried at the fourth month, giving birth to triplets. If he remembered correctly, there were two placentas.

REMOVAL OF THE COCCYX AFTER INJURY.—Dr. GEORGE T. HARRISON presented the three lower bones of the coccyx which had been removed from a patient with the following history: Aged twenty-nine years, admitted to the Woman's Hospital, Dr. Emmet's service, in March, 1881; had been under treatment for the past nine years for uterine disease. Some weeks before, when sitting down, she struck the end of the coccyx on the corner of a chair. She was able to walk immediately afterward, but on the next day movement of the body and of the lower extremities gave severe pain in the region of the coccyx. This continued until she entered the hospital. In June the patient was discharged improved, but returned again in October. She was then unable to sit without great pain, or to stand longer than a few minutes at a time. Dr. Harrison here remarked that this patient had come under his care eight years ago, suffering from retroflexion of the womb, bound down by perimetrial adhesions. He succeeded in restoring the uterus to its normal position, and the patient was comparatively well until the accident before mentioned. Dr. Emmet thought the symptoms were due to perimetrial inflammation, and directed treatment accordingly; but, as no improvement followed, the coccyx was then removed, with the exception of the first bone, which was firmly ankylosed with the sacrum. The bone itself was not apparently diseased.

Dr. DAWSON asked whether, in cases in which motion could be detected in the coccyx, attended by pain and all the symptoms mentioned by Dr. Harrison, which were not relieved by other means, it was justifiable to remove the movable extremity. About a month ago he removed the fractured coccyx from a patient who had suffered for years from pain apparently attributable to a fall, striking the coccyx against the edge of a trunk. He had under care at present a young girl who had for years been treated for uterine disease such as had existed in Dr. Harrison's patient, and had been only partially relieved; but the coccyx was movable, and was the seat of considerable tenderness and pain, following a fall upon that point some years before, and the question had arisen whether the bone should not be removed.

Dr. HARRISON replied that, as the symptoms referred to still existed after relief of the uterine trouble, it would be entirely justifiable to remove the coccyx. Dr. Emmet had observed that in many cases symptoms which were apparently attributable to disease of the coccyx had disappeared on directing treatment to the uterus or its appendages, and he made it a custom, therefore, not to proceed immediately to the removal of the coccyx until it had been determined that the symptoms were not of a reflex nature.

The PRESIDENT remarked that he believed the subject of coecygodynia had not received the attention in this city, and perhaps throughout this country, which it deserved. This might have been due to the fact that many years ago, when the operation was being performed extensively in England, it was found subsequently that it had been done in many cases in which there was no necessity for it, and it therefore fell into disrepute. He believed that the view held by Dr. Emmet—viz., that in most cases in which symptoms of coecygodynia existed they were due to pelvic cellulitis behind the uterus—was, perhaps, open to criticism. He himself was cognizant of several cases in which removal of the coecyx had been attended with the greatest possible benefit, after a great variety of other means had failed to give any relief whatever. He had performed the operation with a successful result in two cases within the past year, all other means having failed. In one case there was found to be fracture of one of the bones, and in the other chronic periostitis, arising from a fall upon the stairs.

Dr. CHAMBERLAIN remarked that, although we should discountenance any unnecessary operative procedure which mutilated the body, he was not aware that any evil result had followed excision of the coecyx, and, the part being comparatively an unimportant one, it might be justifiable to remove it, even though it had not been positively demonstrated to be the seat of the trouble.

HENRY J. GARRIGUES, M. D.,

B. F. DAWSON, M. D.,

FRANK P. FOSTER, M. D., *ex-officio*,

Committee on Publication.

A STATED meeting was held January 2, 1883, Dr. CHARLES C. LEE, President, in the chair.

VESICO-VAGINAL FISTULA, WITH SPECIMEN.—Dr. P. F. MUNDÉ narrated a case as follows: The patient, a mulatto woman, came under his care at Mount Sinai Hospital about two months ago, having been sent from Jacksonville, Fla., by her physician, Dr. Drew. She was delivered of her first child, about seven years ago, with the forceps. Soon afterward there was incontinence of urine. Dr. Drew then first saw her, and made a diagnosis of vesico-vaginal fistula. Escharotics were applied, with the hope of closing it, but failed. When Dr. Mundé first examined the patient the bladder was empty; no urine was escaping through the fistulous opening, and it could not be discovered. Milk injected into the bladder escaped only through the urethra. The uterus and the bladder were bound together by firm adhesions. After the examination the temperature rose to 104° Fahr. At the second examination, made a week or ten days later, he was able to pass a probe into the bladder through a fistulous opening in the cervical canal, the anterior lip of the cervix having sloughed away. The fistulous opening could not be brought into view. An attempt was made to dilate the vagina according to Bozeman's method, and hot-water injections were administered. This treatment was continued for about six weeks. The patient was very sensitive to examination, and each time there was a slight elevation of the temperature. Friday, a week ago, an examination was made under chloroform as usual, and, during gentle traction by the tenaculum on the anterior edge of the funnel leading to the fistula, the fistulous opening was suddenly and unexpectedly brought plainly into view. The following Monday was set for a plastic operation to close the fistula, but within thirty-six hours after the examination the temperature rose to 107° Fahr., peritonitis developed, and at the end of a week the patient died. At the autopsy, extensive old adhesions were found; the uterus was firmly adherent to the bladder. In Douglas's pouch, on the left side, was a laceration of the peritonæum, which had probably occurred during traction

with the tenaculum at the last examination. There was also an abscess of the left ovary, which, however, had not yet ruptured.

Dr. A. JACOBÍ suggested the use of the galvanic-cautery wire in the treatment of these small fistulous openings.

Dr. MUNDÉ remarked that the situation of the fistula in this case was such that its closure with the cautery would almost certainly have resulted in cicatricial contraction of the cervix.

The PRESIDENT had seen a number of similar cases of vesico-vaginal fistula with a pin-point opening, both in his own practice and in that of Dr. Sims and Dr. Emmet, and he had found, contrary to the opinion expressed by Dr. Mundé, that, even when fully exposed to view, it was exceedingly difficult to close them successfully with the silver-wire suture. This difficulty was due to the presence of cicatricial tissue which had been produced by the attempts of nature at repair, or by previous treatment with caustics. His success with the galvanic cautery had not been much greater. With regard to the fatal attack of peritonitis in Dr. Mundé's case, it was evident that undue traction had not been made during the examination, and it was probable that the peritoneal adhesion which had given way, and which evidently was very friable, would have been lacerated under any other slight provocation. In not a few of the cases in which Emmet's operation for laceration of the cervix had been performed by unskilled operators, traction had been so rudely made as to result in a condition of the pelvic tissues which was liable to give rise to peritonitis upon the slightest exciting cause.

Dr. JACOBÍ further remarked that about twenty years ago he had occasion to treat a case of vesico-vaginal fistula in which the opening was quite small, and in that case he was enabled to effect a cure within four or five days by fifteen or twenty applications of a concentrated solution of nitrate of silver, made with a brush. His experience in these cases had not been extensive, but he felt convinced that, had the galvanic cautery been used in Dr. Mundé's case, before the cicatricial tissue had been augmented by the acid caustics, the fistulous opening could have been closed without injury to the cervix. With regard to the readiness with which peritonitis developed, he had examined the condition of the tissues post mortem in a number of cases, and had found the membrane at the seat of the inflammation thickened, of a white color, friable, easily breaking down under the finger, the seat of granular degeneration; and in many cases, doubtless, it would require but the slightest provocation during life to cause the parts to give way, probably resulting in fatal peritonitis.

PNEUMONIA IN THE INFANT.—Dr. B. F. DAWSON presented the lungs of a child that had died of pneumonia at the Foundling Asylum when five weeks old. The right lung presented several spots of lobular pneumonia, and the upper lobe of the left lung was the seat of general lobular pneumonia. The interest in the case turned upon the presence of certain spots very resistant to the touch interspersed throughout the portion of lung affected with the catarrhal inflammation, which he suspected, from their appearance on section, to be of the nature of croupous pneumonia—which was possible in lobular inflammation.

Dr. JACOBÍ understood Dr. Dawson to say that it was not within a few years past that croupous pneumonia had been recognized in children, and then but seldom. He believed this to be a mistake. He himself, as well as most persons, had recognized it a number of years ago, although until recently it had been generally believed to be a rule which had very few exceptions, that the pneumonia of infancy was lobular, while that of adults was usually lobar. This generally accepted view, however, which has prevailed through the present century, is accounted for by the tendency of authors to copy the statements of others rather than to observe for themselves. Some claimed at the present time that the pneumonia of infancy was

monia as compared with lobular pneumonia in children was as one to three, four, or five. Baginsky, of Berlin, in his work on pneumonia, published about a year ago, gave the percentage as 27 to 100. Until a sufficient number of cases had been reported it would be impossible to make an exact estimate of the frequency of the occurrence of croupous pneumonia in children, but Dr. Jacobi thought it would probably be found to be present in about ten per cent. of all the cases.

Dr. DAWSON remarked that he had seen cases of lobar pneumonia in infants, and the point to which he would call attention was not the infrequency of its occurrence, but the fact that in this instance there was evident lobular pneumonia with fibrinous exudation confined simply to the affected lobules.

Dr. JACOBI remarked that lobular pneumonia was just as likely to give rise to surrounding interstitial inflammation as lobar pneumonia was, and even more so. He should, therefore, consider the case one of lobular pneumonia with connective-tissue hyperplasia. He was unable to answer the question of the President as to the reason for the discrepancy in the figures given by different authors regarding the percentage of cases of croupous pneumonia occurring in childhood. Possibly climate and endemic influences had something to do with the difference in the proportion of cases occurring in different countries.

DIPHTHERIA IN THE NEW-BORN INFANT.—Dr. JACOBI related the following case as one which was very rare and interesting, being, however, the second case of the kind which had come under his care: A woman, the wife of a grocer in Thompson Street, menstruated for the last time on the 12th of March, 1882, and gave birth to a child at 11 P. M. on the 2d of November of the same year. Toward midnight of the 2d the midwife washed out the mouth of the baby with a linen cloth which had been washed on the 30th of October, ironed on the 31st, and then laid away with the rest of the child's clothing. During the night it was noticed that the child cried a good deal, and did not swallow. At 11 A. M. of the next day the midwife came again, and found the mouth of the infant of a dark red color, and a dark, almost black, discoloration of the edge of the tongue. This dark discoloration could be washed off. Corresponding with the upper lateral incisors there were two white spots, which were taken by the family to be congenital teeth. During the first day of the child's life, all, or nearly all, that entered its mouth came out again through the nose. On the next day, the 4th, Dr. Rudisch was requested by Dr. Jacobi to see the case. He reported to Dr. Jacobi the following morning that the same white spots remained. Dr. Jacobi then visited the patient, and found the whole of the mouth, the lips, the tongue, and the cheeks covered with a thick grayish-white membrane. Part of the membrane could be wiped off. The baby was hoarse, but there was evidently no laryngeal stenosis. The eyes and the nose were not affected. The baby died on the next day, the 6th of November.

With regard to the surroundings of the patient, the family kept a grocery store on the first floor, and lived on the second floor, occupying the whole of it. While they were not very clean people, the room in which the mother lay was kept very clean. They had a boy, seven years of age, who was in and out all the time, but he did not have diphtheria. They also had a daughter, sixteen years of age, who also showed no symptoms of diphtheria. All the adults in the house were healthy. The mother made a good recovery in the usual length of time. There was no affection of the vagina. Under the same roof was another family, but without children, and they had no diphtheria. In a rear house were three families, but there was no diphtheria, and had not been for some time. The midwife stated that she had not been with sick children, nor with sick women, for a long

time. The mother of the child had always shown great power to withstand disease and hardship. These facts seemed to show clearly that there had been no possible tangible source of diphtheritic contagion, and that there had been nothing in the surroundings of the child which could give rise to the disease. Dr. Jacobi laid special stress upon the fact that the mother showed no signs of diphtheria, or of any febrile disease. He had examined a part of the membrane from the child's mouth microscopically, and found it was diphtheritic.

Dr. WILLIAM H. WELCH, microscopist of Bellevue Hospital, to whom a specimen had been sent for examination, also pronounced the case one of diphtheria, and reported as follows:

"The specimen consists of a small shred of membrane preserved in Muller's fluid. It was examined by tearing out portions of the membrane. It consists of fibrin, pus, and epithelial cells, red blood corpuscles, and granular material. The fibrin is in part delicately fibrillated, in part in coarser bands and irregular shapes, which are usually referred to a fibrinous metamorphosis of epithelial and pus cells (coagulation-necrosis). The pus cells in places are abundant, and stain well with hæmatoxylin. The epithelial cells are flat, part with and part without nuclei. The red blood corpuscles are accumulated in patches, and are shrunken from the action of the fluid used in preserving. The granular material consists chiefly of bacteria, which can be readily stained in fuchsin. Some are round and in colonies (micrococci); others are rod-shaped. The structure is that of a diphtheritic membrane."

Committee on Publication.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

A STATED meeting was held December 28, 1882, Dr. JAMES TYSON, President, in the Chair.

TUBERCULOSIS OF THE SPLEEN, LIVER, AND KIDNEYS.—Exhibited by Dr. SHAKESPEARE. These specimens were presented without a history of the case, and showed exuberant vegetations in pericarditis, abundant miliary tubercles of the pleura, of the liver, of the spleen, of the kidneys, and of the lymph glands in the region of the head of the pancreas. The subject came from the medical wards of the Philadelphia Hospital, and was last under your care, Mr. President, as visiting physician. They are brought to the notice of the society mainly because the autopsy was made this P. M., and because many of the members have not had opportunities of examining such perfect examples of extensive and diffuse tuberculous infiltration without more serious involvement of the parenchyma of the lungs.

Autopsy six hours after death of C. J., colored, aged sixty. Diagnosis: Pericarditis and pleuritic effusion, with strong bands of adhesions between parietal and visceral pleura. Thorax: Left pleural cavity completely obliterated by adhesions. Right pleural cavity contained a large amount of straw-colored serum. The lobes of this lung were compressed against the spinal column, and were atelectatic. The lower lobe was firmly adherent to the diaphragm, and the three lobes were strongly united by adhesions. The parietal pleura was thickened, and everywhere studded with minute gray semi-opaque miliary tubercles; the visceral pleura was in a similar condition, except that the tubercles were less numerous. The cut surface of the right lung presented nothing abnormal save absence of air, but the sense of touch showed beneath and near the pleura a few scattered minute points, much smaller than millet-seeds. The pleura of the left lung was also studded with numerous miliary tubercles, and the tissue of this lung was similar to that of the right. It was, however, crepi-

tant. The pericardial sac contained two and a half ounces of straw-colored serum. The whole heart was covered with an exuberant crop of vegetations. The cardiac walls were perhaps slightly softer than usual, otherwise normal. Abdomen: Peritoneum normal; no effusion. Liver: Slightly enlarged, with surface here and there raised by flat elevations, ranging in size from a hemp-seed to that of a hazel-nut; capsule normal. The nodules were firm, and of a yellowish tint; the intervening tissue was of a dark red. Deep section of the organ revealed similar nodules diffused through its substance, which seemed otherwise firm and normal. The spleen was slightly enlarged, firm, and extensively infiltrated with tubercles. The pancreas was normal, but the lymph glands near it were much enlarged, but neither softened nor caseous. No caseous focus was anywhere detected. The kidneys appeared normal, except for one or two more or less pyramidal yellow points. The case presents several points of interest. 1. Former history unknown. 2. Several aspirations, showing considerable pleuritic fluid. 3. What was the origin of the numerous tubercular eruptions, and, if there was auto-infection, what was its probable source?

Dr. TYSON then gave a *résumé* of the ante-mortem history,* saying that he regretted having to admit that he was less familiar with the history of the case than he should have been, since the patient was in his own wards in the Philadelphia Hospital. He had been previously thoroughly studied by Dr. Bruen, whose absence he regretted, as Dr. Bruen knew so much more about the case. The man had, however, been more than once tapped. He was a colored sailor, aged sixty years. When Dr. Tyson took charge of the ward in September, the man presented the physical signs of double pleuritic effusion, orthopnea, feeble transmitted heart sounds, but no cardiac murmur. There was oedema of the legs. He was tapped with great benefit, and, under a restorative treatment, he rapidly improved, so that he soon became one of the walking cases in the ward, attracting little attention. About December 1st he became very much worse. The orthopnea and other signs of accumulating fluids returned, and so did the oedema of the legs. His urine was repeatedly examined for albumen, with negative results. He was tapped upon the right side, and three pints of fluid removed, with but partial relief. The other side was also aspirated without success. A cardiac friction sound was noted, which seemed to be pleuro-pericardial, but, in the light of the autopsy, it was probably pericardial. He died on the 13th of December. With reference to the case cited by Dr. Formad, it had also seemed to be a simple plastic pleurisy, with feeble, distant heart sounds, with no murmurs, occurring in a case where, after prolonged illness, death resulted from exhaustion. Dr. Tyson had never seen such extensive new formations resulting from serous inflammation, the large lymphoid masses in the abdomen having at first suggested the idea of malignant disease. The patient had a distinctly scrofulous history. The father had died after pleurisy with cheesy deposits, followed by miliary tubercles of the lungs later in life. Four or five uncles and one aunt had all died phthisical, from between twenty to thirty years of age.

Dr. BARTHOLOW asked if the range of temperature accorded with that usually found in phthisical cases.

Dr. TYSON said that in the case related by Dr. Formad the temperature was seldom, if ever, above 101°, mostly below this point. In the case reported by Dr. Shakespeare, he was unacquainted with the temperature record.

Dr. NANCHEDE demurred to the view that repeated tapping had any causative relation to the development of tubercle after

pleurisy, but thought that the chronicity of the affection and altered condition of the pleural sac, which demanded frequent operations, were the real explanations of the alleged fact.

Dr. MUSSER said that a relationship between pleurisy and pulmonary tuberculosis could not be denied, but whether the pleurisy or the tuberculosis be antecedent was difficult of solution. That the former is primary may be inferred from the fact that persons are considered as threatened with phthisis who have subclavian arterial murmurs due to the pressure or pulling on the artery of organized lymph. Likewise are the various friction sounds and exocardial murmurs noted to precede tuberculosis, and especially to occur in those tuberculously predisposed. Examples of both cases have come under his observation. It seemed to him that a primary acute pleurisy was a rarity occurring in a non-tubercular subject. The last series of cases of what would be called primary pleurisy he had seen were in persons predisposed to tubercle, and in some of the cases tubercle subsequently developed. In short, so-called primary plastic pleurisy occurred only in tuberculously disposed individuals; other forms were secondary to some other process, as Bright's disease, septicemia, etc. Trousseau called attention to latent pleuritis with effusion as being often an expression of a tuberculous diathesis, while also a latent pleurisy might occasion development of that diathesis. Two cases illustrating these views had lately come under his notice.

Dr. O'HARA said that, although he had not had much experience with latent pleurisy, he recalled a case of a young man, seen five years ago, where extensive effusion into one side of the chest had unsuspectingly occurred, and, when detected, had been removed by tapping. Apparent recovery then ensued, to be followed in a few weeks by a copious effusion into the other pleural cavity. Tapping was again resorted to, the effusion never recurred, and the patient remains healthy and free from tubercle at the present time. He would like to ask if, when the term "all the serous membranes were affected" was used, those of the brain were included.

Dr. TYSON replied that there had been no head symptoms in the sailor's case. In that mentioned by Dr. Formad, decided mental aberration, demanding watchful restraint, had been present. No inflammation of the meninges had been found, the only disease consisting of a small tubercle starting from the pia mater and dipping down into the brain substance.

Dr. SHAKESPEARE closed the debate by referring to the causes of tuberculosis in general, and its mode of diffusion through the organism. He called attention to the failure in discovering any caseous focus, while admitting the possibility of such, if minute, escaping the most painstaking search. In this and similar cases, all that could be safely said was that the cause could not be found. Assuming, for illustration, that the point in the kidney might have been the origin of the auto-infection in this case, he referred to the communication between the left renal vein and the inferior mesenteric vein, and the direct communication with the portal system thus effected. As to the point raised by Dr. Musser, he believed in plastic pleuritis distinct from tuberculosis. He had examined many cases of serous effusions of pleuritic adhesions, and many had pointed to the formation of tubercle. Authors who have made original investigations on man and the lower animals have also as distinctly recognized a plastic pleurisy without tubercle as they have one associated with this formation. He thought tapping, in a person not predisposed to tubercle, was no more likely to produce this disease than tapping an anasarctous limb. He was well aware of the facts dwelt upon by Drs. Musser and Formad, viz., the association of tapping with tuberculosis and of plastic pleurisy with tubercle, but he believed that the frequency of the association had been exaggerated. He thought, in view of the well-grounded belief that in certain classes of anasarctas as well

* Dr. Formad here related a case of general tuberculosis, and showed the specimen, but, he notes having been forwarded to the Recorder, any fuller account than the remarks of Dr. Tyson is impossible.

as in certain families of men, inflammation tends to linger, to produce accumulations, which are prone to degeneration, and to excite local or general tuberculosis, it is more logical to conclude that, in such cases as above mentioned, there is at the outset a tainted constitution, a soil already sown with the dormant seeds of disease waiting to be awakened to their active processes of destruction by the stimulation of an exciting cause. The more frequent the action of the exciting cause, the more certain is this dormant tendency to be aroused. [Dr. Shakespeare then proceeded to combat the views advocated by Dr. Formad in this debate; owing to their non-reception by the Recorder, Dr. Shakespeare's remarks are also of necessity omitted.]

TWO CASES OF CARCINOMA OF THE STOMACH.—Exhibited by J. H. MUSSER. CASE I.—*Scirrhus of the pylorus; general proliferation of the connective tissue; interstitial nephritis*. When the patient applied at the Medical Dispensary of the University Hospital, May 14, 1882, for treatment, malignant disease of the pylorus and of the lesser curvature of the stomach was diagnosed, on account of the physical signs especially, and of some points in the clinical history. Palpation and percussion revealed a firm, non-pulsatile, immovable, slightly painful tumor, about the size of a turkey-egg, in the middle of the epigastric region, one inch to the left of the median line. When lying down, the abdomen was slightly scaphoid, but the left upper quarter was distended. A curved line, extending downward from the umbilicus to the flanks, represented the lower limit of this swelling, which was soft and resistant, tympanitic on percussion, and, with care, could be discerned as starting from the hard tumor in the epigastrium. In short, it was due to a distended stomach. Although the tumor was not in the position of the pylorus, and although the patient had never vomited, yet pyloric disease was determined upon, because of the gastric distention. On account of the absence of marked obstruction, the position and the occurrence of pain in the lumbar region, disease of the lesser curvature and the posterior wall was decided upon. The autopsy revealed that the malignant growth surrounded the stomach at the pyloric end, but being greater in extent in the lesser curvature. An adhesion to the left lobe of the liver explained the position of the tumor. The patient first noticed the localization of the disease in November, 1881, by the occurrence of pain in the epigastrium following a jar. She noticed that her health had failed three months before, and that menstruation had ceased six months previous to the epigastric pain. Note here the failure of health before any local evidences of disease, not even dyspeptic symptoms. She was a widow, aged forty years, with one child; her health had always been very good, her circumstances moderate, and her habits exemplary. In addition to a constant burning pain, increased by food, her appetite was poor; tongue pale, with enlarged papillae; flatulency was marked, and the bowels constipated. She presented a sallow, cachectic appearance, was somewhat emaciated, extremely anæmic, with cardiac, arterial, and venous blood murmurs, and accentuated second sound. She was under observation until her death, October 17, 1882. The pain and constipation were relieved by treatment, but the course was only downward. In addition, I may note that the cachexia became more marked, and the classical appearance of the face was wonderfully depicted—transverse and vertical lines on the forehead, semicircular lines around the mouth from the alæ of the nose to the chin, and vertical lines on the chin and lower lip. The hue of the countenance changed, growing darker and darker. This peculiar hue of the face Dr. Musser considered the most reliable symptom of approaching dissolution. It was noted one month before death. During the last two months of her illness she suffered much from soreness of the mouth and tongue, without visible lesions; from burning in the fauces, difficulty of

deglutition, acidity, vomiting taking place every third or fourth day of a clear acid fluid, coagulated milk bile-stained, and "coffee-ground material." A painless watery diarrhœa occurred frequently, with tarry masses. Œdema of the feet and ankles took place six weeks before death. The tumor grew in size, and changed position, falling downward. Three days before death it was noted to pulsate, was tender, and was three inches long, extending from the median line to the left, on a level with the umbilicus.

Autopsy twelve hours after death: Extreme emaciation; rigor mortis marked; œdema of feet; heart slightly enlarged, the left ventricle walls 8-75 lines in thickness; heart weighed 7 ounces. Aorta, 1 inch 1-75 lines in diameter, and slightly atheromatous. Deposits of fat along the septum were noted, and the muscular tissue itself was fatty. The stomach was in the position defined a few days before death, was greatly dilated, with the disease at the pyloric end extending along the lesser curvature four, along the greater curvature two inches, and completely encircling the organ. The stomach walls became thickened with much hypertrophied muscular coat as they approached the diseased area. The internal surface of the tumor was flat, elliptical, and defined by an everted lip of varying thickness about four lines high. The surface was uneven, some nodules being half an inch thick. The most central portion presented distinct evidences of ulceration. The liver was rather larger than normal, seemed fatty, and was not indurated. The kidneys were small, hard, and the capsule peeled off with difficulty. Microscopic examination of the stomach, liver, and kidneys, Dr. W. E. Hughes assisting, showed abundant irregularly shaped epithelial cells packed closely in a fibrous stroma, but slightly developed in and containing numerous nuclei. Liver-cells, fatty and pigmented. Proliferation of the connective tissue around the hepatic and portal veins was noted, many nuclei proving its recent origin. The kidney was markedly cirrhotic, the connective tissue being not of recent formation. Note the general proliferation of connective tissue in the organs. No albumin was detected during life in the urine, nor were any renal symptoms noted, yet there was undoubted interstitial nephritis belonging to the variety described by Gull, Sutton, and Mahomed. The mal-assimilation consequent upon the gastric lesion was the predisposing factor in the production of this general change.

CASE II.—*Scirrhus of the pylorus*; symptoms simulating idiopathic anæmia. F. R., aged fifty-four, white, German. Resident of a healthy locality, but much exposed as lumberman during the winter. Addicted to constant use of spirits, malt liquors, and tobacco. Had a fever of six weeks' duration at the age of sixteen years, and eight years ago some pulmonary inflammation. Never had malaria or syphilis. Does not know cause of mother's death; seven brothers and sisters, healthy; father died of old age; his own three children living and healthy. Admitted to University Hospital, December 20, 1878. During the previous winter had numerous gastric attacks, as shown by pain and loss of appetite. In the spring and summer he lost flesh and strength, and was subject to pain in the bowels and in the hepatic area, flatulency, pyrosis, and constipation, but never vomiting. On account of salivation, in June he became especially debilitated. At time of admission, weight 118 pounds; usual weight, 170. Laid on left side, perfectly apathetic, with the physical and mental processes slow of action. Extremities cold, very anæmic, conjunctiva and mucous membrane very pale; sclerotics pearly white; complexion, of a sallow, dirty hue. Palpitation of the heart, dyspnea, and subjective ear-noises were noted; temperature irregular, appetite poor, flatulency and pyrosis; pain and tenderness in epigastrium; no definable tumor, but a sense of induration. Hepatic and splenic

areas of dullness normal. No venous hum. Heart sounds weak. Urine, sp. gr. 1.018, neutral reaction, albumin one blood. No casts, bile or sugar. Phosphates, not in excess. Blood, white corpuscles in excess; red, greatly decreased in number. Ophthalmoscopic examination: Slight retinitis; O. D. pallid; central artery dilated. Venous blood paler than usual. Absorption of choroidal epithelium, allowing choroidal circulation to be seen. Macula healthy; no hæmorrhage throughout fundus. Both eyes present the same appearances. A low typhoid state soon developed, with diarrhœa and excessive flatulence. For three days prior to death, vomiting occurred. He died December 30, 1882. Autopsy: Stomach alone examined. It is to be regretted that the full record was lost. Stomach adherent to liver and transverse colon. Lesser curvature, from pylorus half way to cardiac orifice, infiltrated with cancer, extending two inches over the anterior wall, and at the pylorus encircling the organ. Pancreatic and biliary ducts pervious. Microscopically, the growth was found to be scirrhous carcinoma.

Remarks.—On account of the profound anæmia and the absence of tumor and vomiting, idiopathic anæmia was considered. The examination of the blood and the condition of the eye-ground contraindicated such a diagnosis. The normal size of the liver and spleen and the non-glandular involvement excluded leucocythæmia. It is to be regretted that the exact numerical blood count was not recorded. In this case the lesser curvature was very much involved, and a distinct tumor was absent; quite the opposite of Case I.

TUMOR OF THE BRAIN.—Presented by Dr. A. P. BRUBAKER, for Dr. H. LEAMAN. John Jones, aged fifty-three, laborer. When first seen, the patient was lying on his back, with head drawn backward into the pillow, and complaining of stiffness and soreness in back of the neck. The mouth was widely opened and parched, and the breathing deep and heavy. He was in a semi-unconscious condition, from which, however, he could easily be aroused, but soon relapsed into his former state, which was attended by stertorous breathing. Speech and deglutition were both interfered with, but not abolished. There was involuntary passage of urine, but the bowels were constipated. Venereal ideas were excessive, but accompanied by complete impotence. Voluntary movements of the extremities, and also the power of co-ordination, were considerably impaired. Pulse and temperature were normal. Liquid food was taken with difficulty. His condition had been as described four days previous to my first visit on September 4, 1882. The symptoms gradually increased, and coma supervened, which ended in death, September 17, 1882. The following history was obtained from the family: Twenty-six years ago the patient was confined to bed with "nervousness" for a period of two years, when he passed a calculus about the size of a date-seed; again, a month later, another smaller one was passed. His bladder continued to give him more or less trouble up to death. He had his clavicle broken nineteen years ago, but there was no injury to the head. About sixteen years ago he was suddenly seized, while at work, with a severe headache, and became totally blind, which lasted for twenty-four hours. This was relieved by wet cups to back of the neck. From that time he was subject to what they called "shaking spells." When standing there would be a violent trembling of the knees and shaking of the arms. These attacks occurred about once a month, and occasionally three or four times a day. They increased from year to year in frequency and severity, and appeared to be excited by high winds and storms. In February, 1882, he was seized with paralysis, beginning in the left little finger, thence gradually extending to the ring and middle fingers, until the hand became powerless, but was able to move his arm. Then followed a numbness in the outer side of the left side, attended by impairment of the power

of co-ordination, so that, on attempting to walk, he was compelled to run to keep from falling. He frequently fell in the street, and had to be carried home. Last February loss of speech supervened, which lasted for one month; the patient then began to speak in monosyllables, after which speech gradually returned. Autopsy: Congestion of the entire brain. On removing it, four or five ounces of serum ran from the cranial cavity. Brain substance seemed to be normal. *Remarks.*—The specimen of Sylvius was embedded a tumor about an inch and a half in diameter, which was almost entirely concealed from view by the convolutions. It rested upon the convolutions of the island of Reil, completely disorganizing them. The inferior extremities of the ascending frontal and parietal convolutions were normal. The upper surface of the temporo-sphenoidal lobe was somewhat disorganized. The tumor apparently sprang from the pia mater.

Report of the Committee on Morbid Growths.—A section made from the tumor, presented by Dr. Brubaker, and examined microscopically, showed that the growth was tubercular. Its histological structure is seen to consist of fibrous tissue constituting a reticulum, the meshes of which are filled with lymphoid cells. These appearances are very distinct at the peripheral zone of the tumor, while the center and inner zone are in a state of retrograde metamorphosis, presenting a very granular appearance, scarcely stained by the carmine. The blood-vessels are mostly obliterated, their lumen being filled with coagulated blood or granular debris. December 28, 1882.

ENLARGED LYMPHATIC GLANDS.—EXHIBITED BY Dr. W. H. PARRISH, who showed five lymphatic glands removed from the axilla of a patient whose breast he amputated about nine months ago. The case was then reported at the Obstetrical Society, and was published in the "Medical News" of July 8, 1882. The specimen was referred to a committee, and Dr. Beates made a microscopical examination, and concluded that the growth was an adenoma that had undergone carcinomatous change. Of the enlarged glands presented, three, about the size of an almond, were removed from the axilla; a fourth, of smaller size, from just below the clavicle, and the fifth from the side of the neck, about an inch from the clavicle. The patient presented no cachexia. The specimens were referred to the Committee on Morbid Growths.

EXCERPT FROM THE FERRUGINOUS CORNIX.—Presented by Dr. W. H. PARRISH, who also presented two small growths, each about the size of the last phalanx of the thumb, removed that day with a wire cæreaser. On Christmas eve he saw for the first time a patient of French birth, a teacher, apparently about thirty-five years old. When he entered her room she was in a state of syncope from hæmorrhage from the genitals. The hæmorrhage had, however, ceased. With the application of hot wet cloths over the front of the chest, and by hypodermic injections of whisky and aromatic spirits of ammonia, she in a few minutes revived, so as to be able to tell him that she had not menstruated for three months, when suddenly bleeding began from the womb and continued during the day, with an exacerbation just before sending for him. As the patient's condition was evidently a critical one, he asked the direct question if she had not had, or was not having, an abortion. She answered, "No." He then learned that she was single, and forty-two years old. A digital examination showed an intact hymen, and a substance in the vagina that at first touch felt very like an embryo of about three months. But on further examination it was found to be attached to the lower part of the cervical canal, and that there was another distending the cervical canal. The latter felt still more like an embryo or ovum, and, in fact, in the absence of the one in the vagina, might have at first misled him into thinking that the patient was a virgin. Since then she has been well.

that it was attached. There was no return of the bleeding, and that day, with the assistance of Dr. M. O'Hara, he removed both the growths with the wire, and without etherization or the use of a speculum. A remarkable feature of the patient's history was that she had always menstruated scantily, and at intervals of five or six weeks. Never before had she evinced a tendency to uterine hemorrhage. He was confident that the patient was not pregnant. He presumed that, being virginal, she was approaching the menopause.

C. B. NANCREDE, M. D., *Recorder.*

Reports on the Progress of Medicine.

QUARTERLY REPORT ON MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

No. XII.

By GASPAR GRISWOLD, M. D.

CONVALLARIA MAJALIS.—Dr. Berthold Stiller ("Wien. med. Woch.," Nov. 4, 11, 18. 1882) reports the results of treating twenty-one cases of heart disease with convallaria majalis. He employed the drug in the form of infusion, after the Russian fashion, and has never observed the vomiting or diarrhoea which has been alluded to by some writers on the subject; the taste is bitter, but infinitely less objectionable than that of digitalis. The author observed the precaution of not giving the drug as soon as patients were admitted to the hospital, for the reason that some benefit is always derived at that time from diet and rest in bed, and this improvement might easily be mistaken for good effects from the drug. Taking the greatest care to eliminate all sources of error, the author is able to state positively that in seventeen of his twenty-one cases the drug had no effect whatever upon the frequency or regularity of the heart's action, the respiration, the quantity of urine, the dropsy, or the subjective symptoms of the patients. In nine of these cases digitalis subsequently gave most satisfactory results. In four cases the convallaria produced an effect. In two of these it produced some diuresis, which was not, however, great in degree or sustained during the continuance of treatment. One of these two cases was subsequently much benefited by digitalis. In the two remaining cases the convallaria seemed to have a favorable influence upon the action of the heart, but the result was not striking. Altogether, the author finds himself unable to endorse the enthusiastic praises of the French and Russian physicians. He suggests, as an explanation of the difference between his own results and the more favorable experiences of other investigators, that the convallaria used by him may not compare favorably with that used in more successful cases. He alludes to the superiority of wild digitalis over the garden variety, and suspects that a somewhat similar difference may exist between different kinds of convallaria. He proposes, in further experiments, to employ the French drug. The twenty-one cases of heart disease treated by the author included four cases of mitral and aortic regurgitation, one case of simple mitral regurgitation, five cases of mitral stenosis with regurgitation, four cases of mitral stenosis, five cases of weak heart, with dilatation of the left ventricle, and two cases of exophthalmic goitre. The cases, therefore, represented nearly every variety of heart disease, and the collection presented a fair test of the convallaria majalis.

POISONING WITH CHLORATE OF POTASSIUM.—Dr. E. Zillner (*ibid.*, Nov. 11, 1882) reports an interesting case of poisoning

by chlorate of potassium, with a post-mortem examination conducted by Professor E. Hofmann; following the report are some general comments on the condition of poisoning by chlorate of potassium, its *modus operandi*, etc. The patient was a strong workman of thirty-one years, who applied to a physician to get a prescription for an attack of sore throat from which he was suffering. The physician gave him twenty grammes (3 v) of chlorate of potassium in powder, with the directions to dissolve a small quantity ("as much as would be raised on the point of a penknife") in a glass of water, and use it as a gargle at short intervals. The next day the patient reported himself better. On the third day he was attacked with convulsions at about four in the afternoon; a physician was called, but made a diagnosis of epilepsy, and did not employ any treatment. The patient died soon afterward. An autopsy was made by Professor E. Hofmann, at the instigation of the Sanitary Commissioners, to investigate the cause of death. On examination, a peculiar grayish color of the skin was observed; this same grayish tinge was present over the mucous and serous surfaces as well. The blood in the veins and that which oozed out upon the cut surfaces of the different viscera was of a peculiar brown color, variously described as resembling tobacco, chocolate, or coffee. The bladder contained about eighteen ounces of urine, which was albuminous, but did not contain blood or casts. The viscera generally were normal, with the exception of the brownish look imparted to them by the altered blood in the vessels. The author dwells upon the grayish tinge of the tegumentary surfaces and the chocolate-brown of the blood as especially characteristic; indeed, Professor Hofmann considered the appearance of the skin alone to be pathognomonic of chlorate of potassium poisoning, and, although ignorant of the history of the case, at once suggested the diagnosis when first shown the body. The author further says that chlorate of potassium acts like a number of other substances which, in the presence of organic bodies, give off oxygen; this action is very marked; for instance, in the case of permanganate of potassium. Two changes result in the blood—one chemical, the other morphological. In the former the hemoglobin is changed into an oxidation product called methæmoglobin; it is this which gives the altered blood its chocolate hue. The latter process consists in a deformation and disintegration of the red blood-corpuscles, which is easily appreciable with the microscope. As a result of these changes, the blood can no longer carry oxygen, and parenchymatous changes are produced in the viscera. The kidneys suffer especially, and the urine becomes albuminous and contains casts of pigmentary substance from the altered blood, as well as epithelial casts. Suppression of urine commonly occurs before death. In the case described in this paper the patient died early—before parenchymatous changes had progressed very far; therefore, no casts were found in the urine, although it had become albuminous. The blood changes were characteristic, as has been said. In the patient's possession was found a paper containing still eight and a quarter grammes (3 ij, gr. iv) of chlorate of potassium; he had, therefore, not used more than eleven and three quarters grammes (3 iij, about). The supposition is that he had swallowed most of this instead of gargling with it, and had died of poisoning at the end of about forty-eight hours from the commencement of treatment.

[For the past few years the German journals have been full of cases of chlorate-of-potassium poisoning. In some of these cases the quantity taken has seemed very small from an American point of view. For instance, in the present case three drachms, taken in very small quantities, well diluted, and the administration spread out over a period of forty-eight hours, is taken as a possible cause of sudden death from convulsions in a vigorous adult! The author even takes the case as a typical

one, and comments on it as if the facts were established beyond dispute, and the quantity of chlorate of potassium quite adequate to produce such effects! On consulting the history of chlorate of potassium, we find that Dr. Fountain, in 1861, took at one dose an ounce of chlorate of potassium, to prove the harmlessness of the drug, but died with suppression of urine on the seventh day. The drug in this case was not much diluted, and produced considerable *gastro-enteritis*. Dr. Tully took an ounce of chlorate of potassium at a dose on several occasions, without injury, only observing the precaution of diluting it very freely. Isambert, throughout a long series of experiments on himself, took daily from two to five drachms of chlorate of potassium; he observed, as effects, salivation, diuresis, and gastric irritation, if the drug were not well diluted. Certainly most people who take chlorate of potassium lozenges on their own responsibility consume as much as a drachm to a drachm and a half in twenty-four hours. The patient who is described in the "Wiener med. Wochenschrift" took only three drachms in all, well diluted, and died suddenly in convulsions, without suppression of urine, the bladder containing eighteen ounces at the autopsy. Since the mode of death was so unlike what has usually been observed in cases of chlorate-of-potassium poisoning, and since the quantity taken was no greater than has frequently been administered without causing any untoward symptoms, it becomes a very difficult matter to be sure that death was really due to chlorate of potassium. The author speaks very confidently of the action of chlorate of potassium in causing super-oxidation of the blood by giving up its oxygen in the circulation. The salt is eliminated, unchanged in the urine as long as forty-eight hours after a moderate dose has been taken, and good authorities state that there are no grounds for believing that it can give up its oxygen at the temperature of the body. Years ago Dr. Stevens, Dr. O'Shaughnessy, Sir James Y. Simpson, and other prominent authorities, used to prescribe chlorate of potassium in all cases of dyspnea, whether from cardiac or pulmonary disease, with the belief that it gave up its oxygen in the blood; anemic mothers used to take it in large doses during utero-gestation to prevent death of the fetus from asphyxia. Then came a day when chemists proved that chlorate of potassium could not yield its oxygen at the temperature of the body, and that the whole quantity administered could be recovered unchanged from the tears, saliva, perspiration, urine, and feces. Most physicians in this country have been convinced by these arguments, and chlorate of potassium is scarcely ever given here now with the idea that it will assist the oxygenation of the blood. Lately the Germans have returned to the former opinion, and their journals contain frequent positive assertions that chlorate of potassium *does* give up its oxygen in the circulation; strangely enough, however, this is no longer regarded as favorable, or spoken of as assisting the respiratory process. Instead of believing, as formerly, that free oxygen in the blood relieves dyspnea and supplements physiological processes, they now describe it as changing hemoglobin into methemoglobin, disintegrating the red corpuscles, and producing widespread parenchymatous degenerations! Certainly new experiments are needed to rescue a household remedy from such a confusion of theories.]

THE INFLUENCE OF IODOFORM ON THE MIGRATION OF WHITE BLOOD-CORPUSCLES.—Dr. C. Binz ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," lxxxix, 3, 1882) alludes to two different theories. According to one theory, the vessel-wall is first weakened by the inflammatory process; the increased blood-pressure then forces white cells through the degenerated vessel-wall. According to this theory, the proper treatment for suppuration would be merely to diminish the force of the heart and lower arterial tension, thereby diminishing the blood-pressure which was causing the cells to pass through the vessel-wall.

The other theory attributed the migration of white cells to their amoeboid movements, and did not take account of blood-pressure in the process. This latter theory is preferred by Dr. Binz, and he believes that suppuration should be treated with remedies which restrain the movements of the white cells. These remedies act in two ways—viz., internally and externally. Quinine is the type of the former class, and, when administered in full doses, controls the amoeboid movements of the leucocytes, and prevents their migration from the vessels. Eucalyptol, salicylic acid, and iodoform are good examples of drugs which can restrain the amoeboid movements of the white corpuscles in areas to which they have been locally applied. The author then gives details of some experiments upon the influence of iodoform upon white-cell activity, the frog's mesentery being selected as the tissue to be experimented upon. It was observed that, in the presence of iodoform, the white cells which collected in the capillaries at the point where irritation was applied did not change their shape or undergo amoeboid movement, but remained spheroidal and passive, and could not pass through the wall of the vessel. This effect was observed to be more positive when sunlight had access to the prepared tissue. This is explained by the author on the hypothesis that under the sun's influence a vapor of iodine is evolved from the iodoform, which renders the influence of the latter more active. The author further believes that the power of iodoform to restrain suppuration, by preventing the amoeboid activity of the white cells, is another proof that the emigration of these cells is a result of their own activity, and not of increased blood-pressure.

PHARYNGEAL TUBERCULOSIS CURED BY IODOFORM.—M. Gruenlein ("Union méd.," Nov. 4, 1882) reports a case of military tuberculosis of the pharynx cured with applications of iodoform. A patient who had suffered with sore throat for six months applied for treatment. She was a young woman of twenty-five years—pregnant at the time. Her throat was found to be the seat of a destructive ulceration, involving the pharynx, both pillars of the fauces, and the posterior surface of the soft palate. The uvula was much swollen, and was removed by the author. It was found extensively infiltrated with miliary tubercles, and presenting numerous points of caseous degeneration. The throat was treated with local applications of iodoform, dissolved in ether, and improvement set in at once. In two weeks the ulcers had nearly healed, and in a month convalescence was completed. About this time a swelling appeared upon one of the pillars of the fauces. To this iodoform was applied, as before, but without effect. It steadily increased in size, and finally ulcerated, discharging quantities of cheesy matter. No sooner had the process of ulceration exposed the tuberculous deposit to the direct action of the iodoform than the curative action of the latter began at once to manifest itself. The ulcer rapidly healed, as the previous ones had done, and recovery was brought about in a few days. From this case the author draws the conclusions: 1. That local tubercular processes are curable by the direct application of iodoform. 2. That submucous infiltrations of tubercle are not much affected by applications of iodoform until ulceration has laid bare the deposit, and exposed it to the direct influence of the drug.

VIBURNUM PRUNIFOLIUM.—Dr. O. E. Hepper ("Journ. Pharm. Med.," Oct., 1882) states that he has observed toxic symptoms in cases in which viburnum was being taken in considerable doses. He reports several cases of uterine disease which were being treated with viburnum prunifolium, given in the usual way, when the patients began to complain of dizziness, dimness of vision, dryness of the mouth, and occasional staggering like that observed in locomotor ataxia. These symptoms disappeared as soon as the medicine was stopped, and reappeared when its administration was resumed in the same cases. The author states that

he was in the habit of referring these symptoms to the uterine conditions which he was treating. He considers it very important that physicians generally should be on the lookout to properly interpret symptoms which present themselves in cases which are being treated with *viburnum prunifolium*.

STRYCHNINE.—Dr. J. A. McCorkle ("Proc. of the Med. Soc. of the County of Kings," Dec., 1882) calls attention to a fact often overlooked, namely, that stimulants like strychnine, used very long or in very large doses, ultimately have a depressing influence and exaggerate the conditions for which they were originally prescribed. The author suggests that physicians should be careful that their patients do not continue a tonic too long. Such medicines should be given in such doses as are calculated to raise the depressed functions to a normal standard; as soon as the physiological condition is approached, the dose of the tonic should be gradually diminished, and finally stopped altogether when health is restored. The too-long-continued administration of a tonic like strychnine depresses the nervous system just as over-stimulation of a nerve by electricity exhausts irritability. In the same way a bitter tonic may have relieved indigestion by stimulating the vascularity of the gastric mucous membrane; but the same tonic, given too long, may produce gastric catarrh, and bring on disturbances of digestion worse than those which had been originally relieved through its use. Strychnine has been advocated as a respiratory stimulant by Fothergill; it is believed that, if used too long, it may depress respiration and interfere with the oxidation of sugar in the lungs to such an extent that temporary glycosuria may result. In support of this, cases are on record where sugar has been observed in the urine of those who had been taking *nux vomica* for a considerable period. The author believes that strychnine, in combination with phosphoric acid, is the best respiratory stimulant we have, but that it may do great harm if continued too long. He also believes that it has decided curative powers in diabetes mellitus, but that this disease is still too little understood to permit of our using strychnine in the treatment of it; for we can not decide when we are doing good and when we are doing harm.

QUASSIN.—M. Campardon ("Bull. gén. de thérap.," Nov. 15, 1882) was induced to undertake a series of observations upon quassin, because he found it difficult to induce patients to take such large doses of the infusion or tincture of quassa as he believes are necessary in order to obtain the full tonic effects of the drug. There are two varieties of quassin in the market—the amorphous and the crystalline. Their physiological actions seem identical, but the crystalline form is ten times as powerful; they are both soluble in alcohol, and the color of the solution is not changed by the addition of strong nitric acid. This last fact is useful in detecting adulterations. The author administers quassin in the form of pill; the dose of the amorphous is from twenty-five milligrammes (about one third of a grain) to fifty milligrammes (about three quarters of a grain). The dose of the crystalline form is one tenth as much. Quassin should be given before meals, three times daily. It increases the appetite, and stimulates the nervous system generally; the energy is increased, and capability for work is augmented. If constipation has been present, the bowels act more freely; on the other hand, in diarrhoeas due to relaxation and intestinal indigestion, the passages diminish in frequency and become normal in quality. The urine is increased in quantity, and the expulsive force of the bladder is improved. The action of the heart, the uterus, and the secretion of milk seem not to be materially affected by quassin in medicinal doses. When a large dose is administered—three or four times the ordinary quantity—toxic symptoms make their appearance. The patient experiences a sense of burning and constriction along the whole extent of the digestive

tract; vertigo is complained of, and cramps of muscles may occur. In some cases vomiting and diarrhoea are observed; the urine is passed frequently, and in small quantities, but without pain or burning sensation. The author recommends quassin as an efficient and powerful tonic. His conclusions are based upon experiences in eighty cases, and he states that his results were eminently satisfactory in all but six. In these six cases the expected improvements, for some unknown reason, did not follow the administration of the medicine.

INJECTIONS OF NITRATE OF SILVER FOR CHRONIC DYSENTERY.—Dr. George E. Post ("Lancet," Dec. 2, 1882) reports a case of severe chronic dysentery cured by large injections of nitrate-of-silver solution. The patient, a delicate lady of thirty years, had suffered continually for five months from tenesmus and dysenteric passages following every exertion. Her appetite was lost, and she was much emaciated. At the time when treatment was commenced she was having six or seven stools daily. The first injection consisted of one pint of water containing fifteen grains of nitrate of silver. The second injection was given on the fourth day of treatment, and amounted to two pints of the same solution. Neither was retained more than a minute, on account of the irritability of the rectum. Improvement, general and local, set in at once after the first injection; the appetite improved, and the dejections assumed a more normal appearance. Only the two injections mentioned were administered, the patient being well on the eighth and ninth days. By the fifteenth day she could walk considerable distances without bringing on any diarrhoea.

EUCALYPTUS ROSTRATA FOR DIARRHŒA.—Dr. T. J. Hudson (*ibid.*, Dec. 16, 1882) calls attention to the efficiency of eucalyptus rostrata as a remedy in various forms of diarrhoea. The drug is not new, but receives only cursory mention in the text-books; the marked success of its administration by the author in two hundred cases of diarrhoea last summer convinced him that it deserved to be more prominently brought forward. Eucalyptus rostrata, or Australian red gum, occurs as imported in dark-red, hard masses; its essential principle is tannic acid. The best form to administer it in is the decoction, made by boiling one ounce of the powdered gum in forty ounces of distilled water for about ten minutes, and filtering while hot. A stronger decoction is made for very acute cases, one ounce of the gum being dissolved in twenty ounces of water. Either of these decoctions may be given in half-ounce doses every two hours, the stronger being used in cases where there is a tendency to profuse watery discharges. Where there is much flatulence, a little laudanum may be combined with advantage. The author much prefers the eucalyptus rostrata to the other tannic acid compounds, especially in chronic watery fluxes.

Letters to the Editor.

THE QUESTION OF THE CODES.

614 FIFTH AVENUE, NEW YORK, March 3, 1883.

To the Editor of the New York Medical Journal:

SIR: Together with probably many others, I am disappointed at the incompleteness of the action taken this year by the State Society in regard to medical ethics. In the preceding year, three codes had been under discussion before the society, viz.: 1, The old code, which is that of the American Medical Association; 2, the new code, which is now known as the New York State Code; and 3, the Ethical Declaration and Resolution proposed by Dr. Roosa. While the new code was still a committee report, Dr. Roosa's resolution had been substituted for it; but it was put to vote by the erroneous parliamentary ruling of the then president of the society, and was thereupon adopted. I had been led to believe that Dr. Roosa's resolution would this year be brought up for discussion, and it was with this understanding that I, with many others, voted against the attempt which was made, by those who desired to re-enact the code of the American Medical Association, to repeal the action of 1882. But the consideration of Dr. Roosa's resolution was postponed for twelve months.

I can not agree with those who hold that the code of the American Medical Association needed no other change than that certain consultations which are therein prohibited should be permitted. I am of your opinion, Mr. Editor, that the whole code should be revised; that it is, indeed, an inconsistency that a physician should be debarred from holding a patent while at the same time there is no prohibition against his holding a copyright, etc. The mistake has been made by the friends of Dr. Roosa's resolution of allowing it to be called "no code." This has arrayed against it all those who believe in the advisability of having a Code of Conduct according to which members of a particular organization can be disciplined. In point of fact, the adoption of Dr. Roosa's resolution would enable the society to hold members to a strict account for acts contrary to the spirit of medical ethics which are now practiced without redress. I propose that this declaration and resolution be known, in contradistinction to both the old and new codes, as the medical *Gentleman's Code*—a name which certainly properly designates it, as according to its provisions the society *claims and promises to exercise the right of discipline for all conduct unworthy a physician and a gentleman*. This code will enable each society to keep its members up to its own moral and ethical standard; and it is well known that that standard varies in different localities.

During the discussion before the State Medical Society, several of the members seemed greatly troubled as to what they should do in the seeming conflict between the old and new codes. The Gentleman's Code should have taught them that, so long as they are voluntarily members of the American Medical Association, they are bound by the Code of Ethics of that Association, no matter to what other societies

they may belong which loose regulations. It is not a matter that code, a gentleman may endeavor to have it changed by the association, but will certainly not violate it unless he has first resigned from the association.

Yours respectfully,
LEWIS ELLIOTT.

SMALL AND FREQUENT DOSES.

From Brooklyn, N. Y., February 1, 1883.

To the Editor of the New York Medical Journal:

SIR: Each generation, in a stable state of society, is wiser than its predecessor, from the merely cumulative results of experience, transmitted in the wealth of books and teaching. But, when a new line of thought or a new principle is discovered, it does not commonly become popular or prevalent with the generation that saw its birth. Two or three generations ago the rules for the amount and method of dosing would appall a doctor of to-day. And he would be obliged to allow that, in many cases at least, to die without drugs was the preferable way. This generation is gradually witnessing a change of sentiment, that is all but universal, and it requires no prophet to see that it will be in the next the dominant idea.

Professor A. A. Smith, in the February 10th number of this journal, has struck the key-note of this change in his lecture on "The Frequent Repetition of Doses." But he has also struck a profounder chord, and one that prevails to a much wider extent than might at first appear on the surface.

Let us quote the first instance: "Urticaria is often caused by the administration of *full doses* of balsam of copaiba . . . a single drop of the same drug given every half-hour will sometimes control urticaria." And he adds: "I have no explanation to offer, but I make the statement not alone upon the authority of others; I myself have often observed the efficacy of the treatment."

Again I will quote: "Fowler's solution—half a drop given every half-hour for six or eight doses—will often relieve the vomiting which occurs after a debauch. It will also relieve the morning vomiting of drunkards, and is of decided benefit in the sympathetic nausea and vomiting of pregnancy."

Is there any one who doubts that arsenic in larger doses will produce vomiting very like the vomiting described?

The next preparation of which I shall speak is a solution of the sulphate of atropine, one one hundredth of a grain in a goblet of water, a teaspoonful of which shall constitute a dose. Now, you will often be called to see cases of supposed croup, but which will, in the majority of instances, prove to be false croup of a reflex origin. Ordinarily you will be able to relieve these patients by giving them teaspoonful doses every hour, or half-hour, according to the severity of the attack. If the child's face begins to flush, and *show signs of the physiological effects of the drug*, the tracheal mucus soon becomes reduced in frequency."

Biddle's "Materia Medica" says: "In larger doses it ('Belladonna, the narcotic properties of which depend on atropia') causes constriction of the throat, difficulty of deglutition and articulation, increased heart-action, quickened respiration, elevation of temperature, marked diuresis, nausea, etc." Is not a very large part of this the picture of that same spasmodic croup? If it is not, then I have yet to meet with that complaint.

Again let me quote *verbatim* (omitting only for the sake of brevity), for I could find no better illustrations than those Professor Smith has given: "One of the most frequent causes of vomiting in children is the administration of large doses of ipecac. . . . We are aware that a teaspoonful of the syrup of ipecac is likely to produce emesis; but it is also a fact . . . that a single drop of the wine of ipecac will often arrest obstinate vomiting. It should be repeated every ten or fifteen minutes. . . . A single drop of the wine of ipecac, repeated every fifteen or twenty minutes, will often produce the most marked relief, both from the vomiting and diarrhoea," of children suffering from this disturbance of digestion (see the former part of the statement). It is a fact well known to all practitioners who have given ipecac in large doses that it does not only produce vomiting, as stated by Professor Smith, but also that large, continuous doses

some cases where it fails to produce emesis, and acts as a nauseant and finally as a cathartic.

"I have administered one-fortieth-grain doses of calomel every hour for ten or twelve hours . . . and relieved the headache of syphilis occurring at night. The relief was very marked the second night." It is also a well-known fact that those who have been poisoned by working with mercury are very subject to headache, and that this is as a rule worse at night.

"Nursing children often regurgitate their food. This has been relieved repeatedly in my experience by giving them a teaspoonful of a solution of one grain of calomel to a pint of water, repeated every fifteen minutes."

Both mercury and calomel produce vomiting when given in large doses, or vomiting and diarrhoea may be the result.

"In infantile diarrhoea very minute doses of calomel, as one sixteenth, one twelfth, one eighth grain, every hour or two, are highly efficacious." So says Biddle.

It seems that Dr. Smith has found that one one hundred and twenty-eighth of a grain, given in the same way, has "repeatedly relieved" the same symptoms. The question suggests itself: Might not one sixtieth or even one one hundredth grain of calomel be efficient in syphilitic nocturnal headache? Testing this is better than all the arguing against it or for it, though Professor Smith has thus far failed to try it.

Again: "Where the diarrhoea is accompanied by mucous passages, indicative of a certain degree of inflammatory action, or enteritis, benefit will be derived by the administration of one teaspoonful every hour of a solution of one grain of bichloride of mercury to one quart of water." This is about one two hundred and fifty-sixth of a grain. And he adds: "The full dose for a child is reached in a few hours."

Biddle says of corrosive sublimate: "It acts very rapidly, producing the most intense gastro-enteritis, with violent vomiting and purging, abdominal pain and tenderness, bloody stools, with death from collapse."

We are assured, in the next place, that one two hundred and fifty-sixth of a grain of tartar emetic, given in solution every half hour, "will prove effectual for the relief of the wheezing and cough accompanying a slight bronchitis in children."

Biddle says "the constitutional effects of tartar emetic in small doses are an increase in the secretions and exhalations generally, especially of the skin." But one must remember that the small doses of Biddle are very large doses when compared with Professor Smith's one grain in a quart of water. And yet Professor Smith insists that his statement "is based upon clinical facts."

"A single drop of the tincture of nux vomica, given every ten minutes, will often produce the most marked relief in sick-headache, not of a neurotic origin." This is from Professor Smith. Biddle says: "In somewhat larger doses" (he mentions as high as five drops of the tincture as an allowable dose) "the stomach is disturbed." This is cause enough for "headaches not of a neurotic origin," and it actually does produce them in this way.

"It is well known," says Professor Smith, "that cantharides, when given in large doses, is liable to cause inflammation of the urinary tract; but it has been found that a single drop of the tincture every hour will, in many cases, relieve vesical catarrh."

"For diarrhoea of children, accompanied with slight inflammation, straining, and the passage of jelly-looking matter, but not true dysentery, five drops of castor-oil, given every hour in water, with sugar and guni, is an excellent remedy."

This is, as even the most inexperienced know, the very sort of diarrhoea overdoses of castor-oil produce.

Professor Smith has, in the cases above quoted, departed from the ordinary rule in giving remarkably small doses. This is the first generalization. Again, he has repeated his doses much more frequently than is usually recommended.

Thirdly, he has in no case produced the "physiological action" of the drug. Indeed, it is this very thing we are cautioned to avoid.

In the fourth place, he has based his statements "upon clinical facts," of which he has satisfied himself "that they are not the result

of coincidence, nor moral influence upon the patient," nor any other less tangible reason than the direct effect of the drug.

Of the thirteen cases quoted, the following tabulation may be made:

In three of them he emphatically asserts that the same drugs, given in large doses, produced effects similar to those they cause in minute doses.

In four others, Biddle distinctly asserts that large doses produce similar physiological effects to those caused by the small doses of the same drug. In one other (nux vom.) I have inferred it from Biddle's statement.

In five others, it is a well-known fact, to all conversant with the physiological effects of the drugs, that they produce similar symptoms, when administered in large doses, to the diseases Professor Smith recommends small doses to cure.

Omitting, then, for sake of exactness, the one in question, nux vomica, we have as follows: Copaiba produces and cures urticaria; arsenic causes and cures vomiting from more or less acute gastritis; atropia causes and cures a false croup; ipecac causes and cures vomiting from great nausea; it also causes and cures a certain kind of diarrhoea, and to this might be added that the diarrhoea is most frequently accompanied by nausea; calomel causes and cures night headaches; it also causes and cures vomiting, also diarrhoea; corrosive sublimate causes and cures diarrhoea marked by tokens of acute inflammation; tartar emetic causes and cures a discharge from the bronchi; cantharides causes and cures acute cystitis; castor-oil causes and cures diarrhoea with jelly-like passages.

In every one of these cases, over causes as written, we might write "in large doses"; and over cures, write "in minute doses," and be within the bounds of exact truth and "clinically demonstrated facts."

In every candid mind the question can not help arising, Are these twelve drugs, so widely different in their nature and physiological effects, acting as they do on so many different parts of the organism, the only ones subject to these generalizations?

Does any one else know of any drug clinically proved to cure in minute doses symptoms similar to those produced by the same drug in large doses? Clinically demonstrated facts are in order. What is the breadth of these generalizations?

Yours, respectfully,

M. W. VANDENBURG, M. D.

Miscellany.

BOZEMAN'S METHODS OF TREATING URO-GENITAL FISTULE.—Dr. Bruntzel, of Breslau, in a review ("Centralblatt f. d. ges. Med.," 1883, No. 3) of a brochure consisting of several papers by Bandl, previously published in various numbers of the "Wiener medizinische Wochen schrift," on the Bozeman method of operating for vesico-vaginal fistulae, and on the operation for uretero-vaginal and vesico-vaginal fistulae, remarks that, while Winckel (in Billroth's "Handbuch der Frauenkrankheiten") refers evasively to Bozeman's methods, Simon recommended them very highly to unskilled operators, and Schröder speaks of them very favorably. The latter, however, describes them so briefly that reference must be had to Bandl alone for an exhaustive account of the procedure, which is but little practiced in Germany. Bandl makes the principles clear by numerous cases in which he has operated, quite a number of them being illustrated by drawings to show the relationship of the parts before and after operation. Bozeman lays the greatest stress on the preparatory treatment of the fistula. After cauterization of the raw surfaces with a twenty-per-cent. solution of nitrate of silver, cylinders of hard rubber are used to dilate the vagina. The process of dilatation is continued from three to five weeks, with gradually increased sizes, until the stretching of the vagina required for the operation is attained. At the same time the cicatrices are cut, which sometimes only show themselves to their full extent after protracted dilatation.

The operation is carried out in Bozeman's knee-chest position, under the influence of an anesthetic. Bozeman has invented for this position a particular table and a special vaginal speculum, in order to

make use of as few assistants as possible. The refreshing of the edges of the fistula is done with a knife and with scissors of different curves, and includes the entire thickness of the vesico-vaginal septum. The stitching is done with straight, spear-pointed needles. Silver wire serves for sutures, which are secured by a leaden plate and perforated shot, the former being bent and shaped according to the requirements of the surface upon which it is to rest. In the after-treatment Bandl leaves a self-retaining English catheter in the bladder until the sutures are taken out. Only in small fistulae does he dispense with it entirely.

In addition to his long list of cases he discusses the origin of fistulae, especially uretero-vaginal fistulae, and their treatment. Even where the largest fistulous openings exist, kolpocleisis is avoided, which operation Bandl says is a mistake in surgery. He proves it to be unnecessary by the brilliant results which have been achieved with Bozeman's method by different operators. A comprehensive table of twenty-six operations done by himself closes the work, the minute study of which Dr. Bruntzel urgently recommends.

CARDIO-VASCULAR DRUGS AND POISONS.—M. Germain Sée thus tabulates the chief facts now known about the elective action of these agents:

	STIMULATION.	PARALYSIS.
Cardiac muscle.....	Digitalin.	The same in the second period of action.
	Iodine in small doses.	Emetine.
	Camphor.	Salts of copper, barium, and potassium.
	Caffeine.	Chloral in large doses. Scillain.
Intra-cardiac muscular motor centers.		Sapoin in its last period of action.
		Iodine in large doses.
Intra-cardiac inhibitory centers.	Muscarine.	Atropine.
		Fubarine.
		Sparteine in large doses.
Intra-cardiac ramifications of the inhibitory filaments of the vagus nerve.	Nicotine.	Pilocarpine, second phase of action.
	Pilocarpine.	
	Calabar bean.	
Trunk of the vagus nerve.	Aconitine.	Sparteine.
	Nepaline.	Nepaline, second phase of action.
Accelerator filaments of the great sympathetic.	Apomorphine.	Sparteine.
Medullary inhibitory centers.	Digitalin.	Chloral.
Vaso-motor centers..	Bromide of potassium.	Croton-chloral.
		Hydrocyanic acid.

COLOTOMY.—In the "Boston Medical and Surgical Journal" of February 22, 1883, Dr. J. Collins Warren reports two cases of colotomy, both operations giving only temporary relief. The first case was that of a German girl, twenty-three years of age, who entered the Massachusetts General Hospital with symptoms of disease of the rectum of one year's standing. She suffered great pain on defecation, in consequence of an indurated growth, which an examination showed obstructed the lower portion of the rectum. An incision, embracing all the tissues between the anus and coccyx, and including the lining of the bowel and the skin, gave relief for a week or two, when the symptoms of stricture again manifested themselves, and it was found that the disease had extended above the incision. Colotomy was performed in the manner described by Allingham, special attention being given to antiseptic precautions, as a slight attack of erysipelas had followed the first operation. With the exception of a slight erysipelatous blush there were no unfavorable symptoms, and the patient was discharged from the hospital in thirty days after the operation, with complete relief from suffering, and having two natural movements from the bowels daily. The disease, however, progressed, and she died in six months, being obliged to resort to opiates only a few days before her death.

The second case was that of an infant with congenital abscess of the rectum. In this instance the incision was made in the right groin, in accordance with the so-called paradox of M. Huguier, that the sigmoid flexure is found there in infants. Relief followed the operation; but the child died on the fourteenth day from a progressive emaciation. An autopsy could not be procured; but Dr. Warren thought that the ascending colon had been opened. Considering the fact that the position of the sigmoid flexure, as given by Huguier, is found in a comparatively small percentage of cases, and that marked emaciation occurs when the ascending colon is opened, although the rapid and abundant discharge of feces following the incision made it seem probable to him at the time of the operation that the opening had been made near the fundus of the cul-de-sac. He is of the opinion that the operation suggested by McLeod—viz., to perform abdominal section, when the rectum is wanting, free, and empty the end of the bowel and stitch it to the anal opening, although a severe operation—is to be preferred to all other alternatives.

Referring to the first case, after comparing the procedures employed in America, England, and Germany, in the treatment of cancer of the rectum, Dr. Warren says a linear division of the stricture which he has performed in a number of cases brings only temporary relief. A radical operation can only be attempted, with reasonable hope of success, in the earlier stages of the disease; but it is important to recognize the fact that the terrible suffering peculiar to cancer in this locality can be greatly relieved by an opening in the bowel at some point above.

DR. GARRIGUES'S CASE OF TRANSFUSION.—The New York correspondent of the "Boston Medical and Surgical Journal," who credits Dr. F. C. Valentine with having performed the operation in the case published in our last issue, remarks that, "as the number of respirations had begun to increase before the transfusion was resorted to, it seems probable that recovery would have taken place, without the transfusion, in consequence of the use of artificial respiration and the other ordinary means adopted." We fancy that very few who will take the trouble to read Dr. Garrigues's account of the case will agree with the writer in question.

THE NEW YORK CODE.—It is the opinion of some shrewd observers that the new code will seriously diminish both the consultation business of its supporters and the number of students who will seek instruction in the schools with which they are connected. For honest, truth-loving students of scientific medicine can have no sympathy with those who are willing to degrade their calling by affiliating professionally with medical quacks. On the other hand, the irregular practitioners have given formal notice that they have their own specialists, and that they have no wish to consult with those who are now seeking to obtain their patronage. Thus the advocates of the new code are likely to find themselves in the position of the greedy dog in the fable, who, in snapping at the shadow in the water, dropped the bit he was carrying, and so lost all.—*Medical News.*

NATIONAL SANITATION.—Congress has appropriated \$1,000,000 as an available fund for use in the work of checking the spread of epidemic diseases during the current year, should such action become necessary. We are glad to see that the Marine-Hospital Service is again charged with the direction of the work.

A NEW CITY HOSPITAL IN PHILADELPHIA.—The Philadelphia Medical Times "calls attention to the inadequacy of the present free hospital accommodations in that city, and characterizes them as entirely unworthy of a city of the size of Philadelphia. Added to this lack of hospital room is the fact that the proximity of the Philadelphia Hospital to the Almshouse at Blockley has prejudiced the popular mind against the former institution, which has become associated with the Almshouse, and many of the respectable poor prefer no medical treatment rather than that which is furnished in the same institution with paupers. A petition to councils is now being generally circulated among the physicians of that city, having in view the removal of the Almshouse, and the exclusive use of the present buildings for hospital purposes. It is also proposed, if the city adopts the plan, to set aside enough ground for the erection of a Children's Hospital for Contagious

Diseases—an institution of which the city is greatly in need. The fact that a building site and an appropriation have been obtained in New York, through the influence of the profession, is mentioned as a stimulus to the hopes of some of the faint-hearted in Philadelphia.

A MOVEMENT AGAINST VIVISECTION.—The report of the Women's Philadelphia Branch of the Society for the Prevention of Cruelty to Animals, read at the annual meeting recently, states that the movement against vivisection is to take a more tangible form than heretofore. Arrangements are on foot for holding a public meeting in the latter part of February, and for taking at that meeting the initial steps toward the formation of an Anti-Vivisection Society in Philadelphia. Other means will also be considered for the suppression of vivisection, "that deadliest of all cruelties." Meanwhile, the thousands of sick men and women who could be relieved by an application of the results obtained by vivisection are to be left to die or suffer the tortures of disease. This is the class of people who strain at a gnat and swallow a camel.—*Medical and Surgical Reporter*.

THE ILLINOIS STATE BOARD OF HEALTH.—At the recent annual meeting of the Board, the following officers were elected: President, the Hon. Newton Bateman, of Galesburg; Secretary, Dr. John H. Rauch, of Chicago; Treasurer, Dr. A. L. Clark, of Elgin.

MOUNT SINAI HOSPITAL.—We are glad to learn that this excellent institution is likely to be allotted a considerable share of the profits of the Purim ball, to be held on the 15th inst.

THE UNIVERSITY MEDICAL COLLEGE.—The forty-second annual commencement of the Medical Department of the University of the City of New York will be held at the Academy of Music on Tuesday evening, the 13th inst., at eight o'clock.

THE NORTHWESTERN MEDICAL COLLEGE.—We are indebted to Professor J. P. Chesney, Secretary of the Faculty of the Northwestern Medical College, of St. Joseph, Mo., for a copy of the "St. Joseph Herald" containing an account of the commencement exercises of the college, which took place on the 20th ult. The members of the graduating class were as follows: S. A. Allen, Iowa; John W. Bullard, Nebraska; Noah Boaz, Missouri; Benjamin Cope, Kansas; A. J. Chamberlain, Iowa; William S. Chenoweth, Indiana; John J. Evans, Missouri; Alfred N. Fisher, Missouri; Benjamin F. Jones, Kansas; John C. Jones, Missouri; William T. Jeffries, Iowa; George C. Potter, Missouri; Isaac E. Stryker, Kansas; Samuel A. Wright, Iowa; Hugo Mager, Wisconsin; C. B. McCollm, Iowa; George W. Pumphrey, Kansas; E. O. Barker, Nebraska.

THE AMERICAN VETERINARY COLLEGE.—The eighth annual commencement of this institution was held on the 28th ult. The following is a list of the graduating class: Harry Louis Alderman, William Henry Arrowsmith, Henry William Bath, William C. Bretherton, Eugene Burget, Lemuel C. Campbell, William Dana Critcherson, Irving S. Denslow, Christmas Evans, Julian Edward Gardner, Franklin Joseph Hanshaw, Joseph R. Hodgson, Fred. Willis Huntington, Samuel K. Johnson, Franklin May Kain, Richard Kay, Arthur B. Morse, John Allebaugh Myers, W. Bertram Carnes Noyes, William Hamilton Pendry, Austin Peters, B.S., James F. Ryder.

The gold medal offered by the New York State Veterinary Society for the best examination in practice, and a prize of a case of instruments for the best anatomical preparation, were awarded to Mr. Kain; and Mr. Hanshaw took the Trustee gold medal for the best general examination.

BLACK SPONGES.—It has been thought that the abnormal color sometimes presented by organic fluids in a pathological condition, also observed on bandages and different articles used in dressing, is due to their developing different fungi or microphytes. The same fact explains the singular phenomenon exhibited by toilet sponges, when their whole surface becomes black. M. Rapin, at a meeting of the Vaudois Medical Society, showed a specimen of these black sponges, which a lady had brought to him in great fear that it would give her a skin disease. M. Rapin calmed her fears by assuring her there was no such danger; but, not knowing how to explain the change of color in the

sponge, he handed it over to M. Dufour, who made a microscopical examination of it. The result of his examination is published in the "Revue médicale de la Suisse Romande." The blackness is owing to the development of a small fungus in the chitinous fibers of the sponge, where it produces numerous black spores, which become agglomerated, and form, with other organic debris, a compact mass. This fungus determines a peculiar alteration of the chitinous fibers, which also become black. In botanical classification this fungus belongs to the genus *Torula*, but differs from all other species of this genus. M. Dufour proposes for it the name of *Torula spongicola*. The presence of this fungus in a single sponge suffices to infect all other sponges that are near it. It can be cured, as well as prevented, by use of the ordinary disinfectants, such as a concentrated solution of carbolic acid, or boiling water.—*British Medical Journal*.

PAPERS saturated with fuchsin solution made yellow with sulphuric acid are recommended by Dr. G. Kroupa as very sensitive tests for gaseous ammonia. Ammonia invariably turns them red.

DEATH OF PROFESSOR VON HECKER.—Professor Carl von Hecker, of Munich, died recently at the comparatively early age of fifty-five. His contributions to the literature of obstetrics and gynecology are numerous and of great value. His continued activity, nearly up to the time of his death, is evinced by the fact that the last number of the "Archiv für Gynäkologie" that has reached us contains an elaborate report by him on the recent work of the Munich Lying-in Hospital.

DEATH OF M. SÉDILLOT.—The death is announced of M. Charles Sédillot, at the age of sixty-nine. M. Sédillot was well known for his "Traité de médecine opératoire."

DEATH OF PROFESSOR VON SIGMUND.—Professor Von Sigmund, the well-known Vienna syphilographer, died recently, at the age of seventy-three.

DEATH OF DR. A. B. DE LUNA.—On the 2d inst. Dr. Abelardo B. de Luna died, while yet but little past thirty years of age. Dr. De Luna was of Spanish descent, and will be remembered as having done some very creditable work in the way of translating the writings of several American physicians into Spanish.

NAVY INTELLIGENCE.—The remains of the late Medical Inspector B. F. Gibbs, brought home on the Nipic, are understood to have been sent to Georgetown, D. C., for interment. — Surgeon T. N. Penrose and Passed Assistant Surgeon D. M. Guiteras are among the officers of the Swatara, which left Fort Monroe February 26th, bound to Cayenne, all ports on the Spanish Main, Aspinwall (the latter part of April), up the West Gulf Coast to Vera Cruz, and then to Key West. — A board for the examination of candidates for admission to and promotion in the Medical Corps of the navy, consisting of Medical Director P. J. Horwitz, President, Medical Inspector J. C. Spears, Surgeon J. H. Clark, and Surgeon J. Rufus Tryon, met in Philadelphia on the 1st inst. — Passed Assistant Surgeon Edward H. Green has been ordered to duty at the Museum of Hygiene, Washington. — Passed Assistant Surgeon N. McP. Ferebee has been ordered to the New York Navy-Yard.

ARMY INTELLIGENCE.—*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 17, 1883, to March 3, 1883.* — CLEARY, PETER J. A., Captain and Assistant Surgeon. Granted leave of absence for four months on account of sickness, to take effect January 3, 1883, in extension of his authorized absence on certificates of disability. Par. 6, S. O. 40, A. G. O., February 16, 1883. — HEIZMANN, CHARLES L., Captain and Assistant Surgeon. To be relieved from duty in the Department of the Columbia. S. O. 12, Department of the Columbia, February 8, 1883. — TESSON, LOUIS S., Captain and Assistant Surgeon. To be relieved from duty at Fort Clark, Texas, and assigned to duty at Fort Ringgold, Texas, as post surgeon. Par. 5, S. O. 20, Department of Texas, February 21, 1883. — BURTON, HENRY G., Captain and Assistant Surgeon. The leave of absence granted October 2, 1882, is extended two months. Par. 2, S. O. 49, A. G. O., February 28, 1883.

Lectures and Addresses.

ABSTRACT OF

THE CARTWRIGHT LECTURES

ON THE RELATIONS OF MICRO-ORGANISMS TO DISEASE.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

BY WILLIAM T. BELFIELD, M. D.

CINCINNATI.

LECTURE III.

TUBERCULOSIS, RECURRENT FEVER, VARIOLA, SCARLATINA, ETC.

THE lecturer began by stating that scarlatina and diphtheritic scarlet fever were now classed among the so-called putrefactive fevers, and that septiciæmia and puerperal septiciæmia seemed also to be related to the other fevers of this class, while the micrococci found in the pustules and blood in variola were apparently identical in form with those of septiciæmia. It was asserted that micrococci could also be found in the blood of patients with gonorrhœa, and, though experiments showed the probability that these were capable of transmitting the disease, yet the fact could not be said to be decisively established that they were its real cause. But about one disease there was no question, and that was what was known as anthrax, or splenic fever, or malignant pustule, or charbon, etc., which was so fatal in sheep, cattle, and other animals. This disease was not only found associated constantly with a bacillus, but it had been proved that this was the cause of it. This was the only disease that was proved to be caused by bacteria, and it was the one that was therefore constantly referred to by pathologists as going to prove the probability of the bacteria found in other fevers being their cause. Anthrax was both contagious and infectious, and it was endemic in certain parts of Europe, but sporadic in the United States and in other countries. It was often very fatal, and might be contracted by man by contact with affected animals, or by eating their flesh; and the spores of the bacilli retained their vitality for a long time, and were not affected by changes of temperature or climate.

When, therefore, we reflected on the close analogy and the clinical resemblance of anthrax to certain infectious diseases; since they, too, occurred sporadically or in epidemics, and were not influenced by climate, or season, or heat, or moisture; while they had fixed periods of incubation, ran definite courses, and were self-limiting, the question was apt to be suggested whether there was not really something more than the dream of a pathologist in this theory of bacteria being the cause of these analogous diseases. This analogy proved nothing, however, and, before accepting this theory, the matter must be as carefully investigated in each disease independently as it had been in the case of anthrax.

In regard to miliary tuberculosis, all pathologists were agreed that this disease in man was identical with the same

disease in rabbits, guinea-pigs, dogs, cats, etc., and it was characterized by aggregations of miliary tubercles in any of the organs of the body. Though this disease was now and had long been supposed to be contagious, yet the evidence on this point could not be said to be decisive. Inasmuch as tuberculosis was known to be caused by non-specific and irritating substances, there was no proof that the bacteria found were the sole cause. It had been shown that such substances as pieces of paper, thread, glass, dust, etc., if placed in contact with the peritonæum so as to irritate it, might cause an eruption of miliary tubercles which differed in no respect from those found in all other cases. When this fact was first discovered, some pathologists maintained that these tubercles were histologically different, but further observation had proved their identity. Others said that spontaneous tuberculosis differed from other varieties, in that it was not transmissible by inoculation. But the falsity of this assertion was proved by experiments on animals. Then arose another school, whose champions were Cohn and Niemeyer, who denied the specific nature of the disease altogether, and contended that it was only an inflammatory product, and with them originated the phrase, "No inflammation, no tuberculosis." But experiments soon revealed certain facts which demolished the Cohn-Niemeyer theory completely. It had long been observed that animals which were not especially prone to tuberculosis in their free state became so when kept long in confinement, and it was often noticed that among tame animals kept in physiological laboratories there was an excessive mortality from this disease. It seemed, therefore, that the disease was transmitted by something which was derived from the cages. And when rabbits and guinea-pigs were isolated, and then inoculated by mechanical irritants, no tuberculosis followed in a single instance, thus disproving Cohn's theory.

Then it was said that tuberculosis began in the intestines, and not in the lungs as a rule. But this was disproved by the following experiment: A certain number of healthy rabbits were confined in a room into which the breath of a number of tuberculous patients was directed, while an equal number of rabbits were confined in a second room so protected that no exhalations of any kind could enter; and then the animals were watched. Of those in the first room several died of tuberculosis in the course of a few months, but none of the others showed any indications of the disease. It was also shown that the simple inhalation of the dry sputa of tuberculous patients would give the disease to dogs, but saliva that had been boiled or acted upon by corrosive sublimate was found to be innocuous, both by inhalation and by subcutaneous injection.

Then, inoculations of tuberculous matter into the eye of animals gave marked results. It was found that when the force of the inflammation at the beginning, due to the irritation of the inoculation, had subsided, either under the influence of atropine or spontaneously, the eye would remain perfectly clear and of normal dimensions for many days; but all at once, between the twentieth and thirtieth day, there appeared on the iris a number of small, grayish tubercles, which soon increased in size, and then became caseous; and,

if the animal were killed, similar tubercles would be found in the lungs and lymph glands. After all these, and numerous other experiments pointing the same way, it seemed impossible to discuss any longer the question of the infectiousness of tuberculosis, and the theories of Niemeyer could not be maintained to-day with the knowledge that had been obtained within the past five years. And Cohn himself acknowledged his former error when he said, in 1879: "There is scarcely a pathologist to-day who will deny that tuberculosis is a contagious disease." Though almost every pathologist was convinced of this fact, yet it was not the case with some of those physicians who regarded pathology as altogether extrinsic to clinical medicine. There were always certain people who could not be convinced of anything. One of this class of physicians would say that, if tuberculosis were really so infectious, he could hardly see how any of us were alive. But he might say the same of scarlet fever, or diphtheria, or many other avowedly infectious fevers to which the physician is frequently exposed. And it might also be objected that doctors and nurses did, in fact, occasionally contract the disease from patients. One seventh of the whole human family contracted it in some way. The fact of its being contracted by one from exposure to a person who had the disease could not be actually demonstrated, because during the long period of incubation, before any significant signs of the disease could appear, the person might have become infected from other sources. It had been found to be from two to four weeks after exposure before any signs of the disease appeared in rabbits, but in the human being the infecting matter might exist latent in the lungs without giving rise to any suspicions of its presence, and months, or even years, might elapse before any physical signs would show that the disease was fully developed. It was, therefore, practically impossible to trace the disease in man to the true source of infection.

Again, an infecting agent was not always capable of transmitting a disease to every animal with which it came in contact, but there must be a suitable soil for the reception of the infecting material in order for it to develop. For example, the herbivorous animals were especially susceptible to anthrax, but all rabbits and all sheep were not susceptible, for a certain number would resist every effort at inoculation. Dogs, on the other hand, enjoyed an exceptional immunity from this disease, yet very young dogs could often be inoculated. Again, the susceptibility to the disease varied in the same animal at different times, and the severity of the attack varied in different animals after they had contracted it. But wherein this diversity of susceptibility consisted we did not know. We only knew that, while the disease might be given to a healthy animal, yet every healthy animal was not liable to contract it. It seemed probable, indeed, that the general law of the survival of the fittest was at work here, and was, from generation to generation, slowly but surely eliminating those that were most liable to the disease, and that at length none would be left to perpetuate it, and so it would at last die out.

The name of Koch had not heretofore been named in this discussion designedly, because the lecturer did not want

to convey the idea that the popular impression that Koch discovered not only the bacillus of tuberculosis, but also the infectiousness of the disease, was a true one. The contagiousness of phthisis was acknowledged five years before Koch's published report of the discovery of the bacillus. The question now with most of the German, French, and Austrian pathologists was not whether tuberculosis was contagious, but whether the bacillus of Koch was the contagious agent.

Numerous examinations of tuberculous material by various observers had already revealed occasionally the presence of bacteria, but there was great lack of evidence in support of the theory that these were the cause of the disease, when Koch, in his quiet, unostentatious way, read at a meeting in Berlin a paper which startled the world, and within two hours the news was telegraphed all over Europe that tuberculosis had been proved to be caused by a distinct variety of bacterium, and that the disease could not occur without the presence of this organism. When such a man as Koch made a statement of this kind, it could not be passed by as one hastily made and of doubtful truth, for it was a remarkable fact that, although he had been for the past eight years almost constantly talking and writing on this subject, he had never as yet been detected in a single error of observation. That Koch fully appreciated the situation, and the importance of accuracy in statement, was shown by the course he took in this matter. Having once discovered the presence of the bacillus tuberculosis in tuberculous tissues, he did not at once blazon the fact abroad, but he kept it to himself until he had satisfied himself that this was the case in all tuberculous tissues, and that these bacilli could be cultivated outside of the body, and then could be inoculated so as to transmit the disease. And he found it a fact that these bacilli were present in all tuberculous patients, and were never present in others. But then the crucial test remained to be tried, and he performed it thus: He first propagated tuberculous matter under his own observation, and then he saw to making it perfectly free from any foreign materials; and he carried the propagation on successively from the first to the eighth generation, occupying in this a period of six months, and with these isolated descendants of tuberculous tissue he finally inoculated two hundred animals, such as rabbits, guinea-pigs, white rats, field mice, and dogs; and, on killing these animals after a considerable lapse of time, he found tubercles and the same sort of bacilli in them in every case. After two years of such careful investigations he at last quietly announced his opinion in a very modest way.

One could easily see, therefore, that a mature statement made by Koch was not to be classed with the hastily formed opinions of other pathologists. If veracity were accorded to him, there was only one possible escape from the conclusion that the bacilli tuberculosis caused tuberculosis, and that was, that he had committed some subtle error either in manipulation or in observation while making his experiments. But, if he had, this was the first error he had been known to make, and so it was altogether improbable that he had been at fault here. Yet, however sure we might be that his work was free from errors of manipulation and ob-

servation, we must, before accepting them as such, wait until other investigators had successfully repeated his experiments with similar results; and, until such investigations had been made, we might fairly decline to accept Koch's conclusions, because this might have been his first error. Koch stated that he found the same variety of bacillus in every animal he examined dead of the disease, and also in the sputa of these animals, but he never found it in others. But a later observer stated that in some cases he could not detect the bacilli in the sputa, and in some tubercles he could not find them. But this was probably because at the time of the examination the bacilli were already to a great extent deprived of their vitality, and hence were insufficiently stained by the coloring fluid, which only brought out the living organisms. The latest observations by European investigators confirmed the statements of Koch.

[The lecturer at this point said that he would have to postpone any further remarks on this subject, as his voice was giving out, and he wished to keep what was left to explain a few pictures he was about to throw on an illuminated screen, illustrating the different kinds of bacteria found in different diseases. The pictures were all photographs, and hence faithful to nature:

1. The first picture showed the beginning of a pyæmic abscess in the heart muscle, where a minute vessel was plugged with pus corpuscles and micrococci, which were invariably present in every abscess.

2. An advanced stage of a broken-down abscess, where the micrococci not only filled the cavity, but were extending into the walls of the abscess.

3. A piece of skin just beyond the advancing edge of an erysipelatous inflammation, where micrococci were always found, though it had not yet been demonstrated conclusively that they were the cause of the erysipelas.

4. Bacteria from a case of pneumonia. In a few cases where observations had been made, micrococci had been found at the edge of the inflammatory process as a sort of advanced guard, just as in erysipelas.

5. A section of the liver from a rabbit dead of anthrax.

6. A section of a kidney from a patient dead of small-pox, showing a vessel filled with micrococci, magnified one hundred diameters.

7. The same magnified seven hundred diameters, showing the individual organisms in the vessel. But, as no inflammatory action was shown in the tissues immediately surrounding these organisms, it was nearly certain that they were post-mortem appearances, and had no existence during the patient's life.

8. *Spirillum* bacilli of recurrent fever, found in the blood.

9. A piece of the spleen of a rat dead of anthrax, illustrating how it was even possible to recover from these diseases after the bacteria had gained a foothold in the system. It was known that after a time these anthrax bacilli died spontaneously, and here you could see those which were dying only indistinctly stained. This disease was not universally fatal, and finally disappeared, because the amount of carbonic acid in the blood was increased in septic diseases as a result of putrefaction, and it was probable that these

organisms are destroyed by this carbonic acid which they themselves induced.

10. Bacilli malarie of Klebs, consisting of minute rods distinguished by a black dot at each end, while the body itself was almost invisible. Nothing definite was known of the relation of these to the cause of malarial fever, but that they did exist in the blood of patients with this disease there was no doubt, and it was also true that they were found to disappear after administering quinine. But that quinine was the actual cause of their disappearance was not absolutely proved by this fact.

11. Illustrating the appearance of the liver in a case of typhoid fever, showing a capillary vessel filled with bacteria. This also was a disease characterized by the presence of a particular organism, but more than this could not be said. The form of this micrococcus was perfectly characteristic, and it was a form not found in the body of a patient dead of any other disease.

12. A section of a kidney from a patient dead of diphtheria of the bladder, the intercapillary network of the kidney being filled with masses of bacteria. These bacteria were not found in the tubules, but rather in the vessels themselves, and this, therefore, would seem to indicate that they were not the product of a local inflammation, but of a general infection.

13. The same section of liver of a typhoid-fever patient as shown in the picture before the last, but magnified not one hundred, but seven hundred times. The oblong bodies of the bacteria could easily be seen here.]

LECTURE IV.

THE BACILLUS TUBERCULOSUS: INFECTION IN GENERAL: THE ECONOMIC BEARINGS OF THE SUBJECT.

IN the first part of the lecture the subject of the relation of bacteria to tuberculosis was continued. Until we could otherwise explain the fact that tuberculous matter, in however minute quantity, when introduced into the anterior chamber of the eye of the rabbit or other animal, was followed by local and general tuberculosis after an interval of three or four weeks; and until we could explain how it was that the injection of the sputum from tuberculous patients caused tuberculosis, while the injection of corrosive sublimate or other such poison, or of the sputum from a patient not tuberculous, did not produce tuberculosis; until we could explain how the inhalation of putrid sputum from a tuberculous patient caused tuberculosis even in dogs, while the inhalation of sputum from a patient sick of some other disease did not cause tuberculosis; until these facts were otherwise more satisfactorily explained, we must concede that tuberculosis was an infectious disease. By this it was not meant that it affected every animal alike, but only certain animals predisposed to it. The investigations of Koch in this direction were referred to, and the conclusion was reached that clinical observations, so far as they had any bearing upon the question at all, went to confirm his results. While his essential statement that the bacilli induced the disease could be confirmed only in those cases and under circumstances for isolating the bacilli and injecting them into the

animal to be experimented upon, yet his preliminary statement that the bacilli were always present in tuberculosis certainly fell within the range of a considerable number of critics, and the results of different observers so far almost uniformly confirmed his original assertion that tubercle bacilli were to be found in the sputum in most if not all cases of pulmonary tuberculosis, and what was far more significant was the fact that thus far this particular bacillus had not been found in any other sputum than that from a patient suffering from this particular disease.

Up to the present time the presence of the bacillus in the sputum had possessed no direct practical value in the diagnosis of pulmonary tuberculosis, for, in the cases in which it had been detected, the diagnosis had been made previously from the physical signs. Whether or not the bacillus would be found in the sputum of patients liable to or suffering from the commencing stage of tuberculosis, before the physical signs of the disease became manifest, was a question to be decided in the future. In this connection Dr. Belfield mentioned the fact that the sputum of twenty hospital patients in Germany was examined by Dr. Councilman and himself, with reference to the presence of the bacillus tuberculosis, and the parasite was found in each of the twenty cases. Afterward, on comparing the result of their observations with those obtained on physical examination by the physicians of the hospital, it was found that all but two of the patients were known to have been suffering from pulmonary tuberculosis; and that, in the case of these two, the physical signs were only those of chronic bronchitis. Had an autopsy been obtained, it was not impossible that tuberculosis would have been found in these two cases also, for it was well known that pulmonary consumption often existed for some time before attention was called to the presence of any physical signs of the disease. Whether the presence of a bacillus similar to that found in the tubercles connected with pulmonary tuberculosis also existed in other tubercular deposits throughout the body, was a question which had not yet been determined with absolute certainty. Fränkel had found the bacilli in laryngeal ulcers of tuberculous patients, but had failed to find them in syphilitic and other laryngeal ulcers.

There was a proneness of some animals, an adaptation of their tissues, favorable to the growth of certain of these organisms. For instance, the bacillus anthracis and the bacillus tuberculosis were rarely found in the body of the dog. The theoretical explanation, based upon a difference in the size of the lymph-channels in different animals, lacked practical demonstration.

Many questions of interest arose in connection with the subject of the etiological relation of bacteria to tuberculosis, but time would permit of the mention of but one, namely: the possibility of infection from tuberculous meat and milk of cattle affected with so-called "pearl disease." But, even though it could be proved that the subcutaneous injection of such meat or milk would produce tuberculosis, it did not follow that its introduction through the alimentary canal would be followed by the same result. Koch found, five years ago, that the mouse was so susceptible to anthrax as to be a reliable agent in testing the strength of anthrax ma-

terial when introduced subcutaneously, yet attempts to induce the disease in mice by feeding them with anthracis tissues and spores proved unsuccessful. The explanation might lie in the general acidity of the gastric and intestinal secretions of the carnivora, but, whatever might be the explanation, the fact remained. Virchow believed it had not yet been proved experimentally that tuberculosis could be induced in animals by feeding them with the meat and milk of cattle suffering from tuberculosis. Although the question of infection through the alimentary canal had not been positively decided in the affirmative, the speaker thought that, in view of the fact that so many children, especially those artificially fed, died of intestinal tuberculosis, and the fact, as had been stated, that thirty per cent. of the cattle in certain herds in this State were affected with tuberculosis, it would be well to make further investigations into the subject.

Dr. Belfield then reviewed the experiments of certain investigators, notably those of Büchner, with reference to the possibility of transforming a bacterium capable of producing infection into a harmless one by successive cultivations, and arrived at the conclusion that the apparent success in this direction had no foundation in fact, but rested upon faulty methods of culture and other circumstances constituting fruitful sources of erroneous conclusions. The attempts made by Pasteur to modify the degree of virulence of bacteria by exposing them to unusual influences he believed to have been equally inconclusive. It seemed that the apparent modification of function, through the influence of oxygen, could be obtained by simple dilution of the original organism.

Before fully entering upon the subject of the possibility of procuring immunity against the infectious diseases by inoculation, we should remember that immunity against the infectious diseases in the ordinary sense of the word was relative, not absolute. An attack of small-pox, of scarlatina, of measles, etc., while it usually gave the individual immunity from the disease for the future, did not always do so. In discussing this subject, the experiments regarding anthrax were taken as an example of those upon all the infectious diseases. Pasteur's theory might be briefly and fairly stated as follows: That immunity against anthrax, as against other infectious diseases, might be secured by one attack of the disease; the same effect might be obtained as in variolation of the human subject, by harmless inoculation with the specific virus after exposure to unusual influences whereby its effects upon the animal were rendered less dangerous. In regard to this theory, Koch remarked that, although some of the infectious diseases occurred in some animals but once as a rule, yet no immunity was secured against others by the first attack, as erysipelas, gonorrhoea, recurrent fever, etc. Anthrax itself not infrequently occurred twice in the same individual. Löffler, Koch's assistant, inoculated fifty-two rats with the fresh virulent material of anthrax. Thirty survived the first inoculation, twenty-three the second, thirteen the third, three the fourth, and one the fifth and sixth. Koch reminded Pasteur, therefore, that, even though the animal survived the virulent inoculation, it did not thereby secure immunity against

subsequent infection with anthrax. Again, Koch called attention to the fact that immunity against subcutaneous inoculation did not necessarily prove immunity against infection through the mucous membrane, especially through the alimentary canal. Certain experiments by Pasteur were referred to in which he seemed to have demonstrated that sheep at least might acquire increased power of resistance to subcutaneous inoculation with anthrax, but he also demonstrated, at the same time, that his protective "vaccination" destroyed almost as large a percentage of animals as usually died from spontaneous infection. Since that time, however, his results seemed to have been more favorable, but the effect of his virus seemed by no means to be uniform.

In reviewing the subject-matter presented in these lectures, the author said that the germ theory assumed, as he understood it, that all infectious diseases were caused by the vital activity of parasitic organisms, and, besides the facts already established in support of the theory, there was also certainly strong presumptive evidence thereof, such as regarded a stage of incubation, the unlimited reproductive power of the virus, and the cyclical course and self-limitation of the disease.

The stage of incubation could not be explained by the mode of action of any unorganized virus or chemical compound with which we were acquainted, all of which began to manifest their effects upon the animal so soon as absorption occurred, the period varying with the rapidity of access to the circulation, according as the alimentary canal, the skin, the lung, or the subcutaneous tissue was the avenue of approach. Certain poisons, even the so-called organic ferments—ptyalin, pepsin, and trypsin—began to manifest their influence immediately upon contact, and, while they might cause the phenomena of septicæmia, they did not possess a stage of incubation.

Another fact in the history of many of the infectious diseases was an unlimited power of reproducing the virus, which could not be attributed, as had just been said, to the agency of an unorganized poison, or even to that of an organic ferment. Illustrations in proof of this statement were quoted. The virus of the so-called infectious diseases must, then, be something capable of reproduction, and reproduction was at present regarded as characteristic of an organism; no unorganized poison, no acid, base, salt, alkalioid, or ferment was at present known which was capable of manifesting the phenomena shown by the virus of syphilis, variola, scarlatina, etc.

Reference was made to the conditions under which the bacillus anthracis was capable of sustaining life and multiplying, conditions pertaining to temperature, moisture, etc., and there was a wide field open for future study in this direction with regard to the bacilli upon which other infectious disease might depend for their causation. The power of inheriting immunity from certain of the infectious diseases was also referred to, an example of which seemed to belong to syphilis. It was the universal testimony that this disease was most virulent immediately after its introduction among a people previously unacquainted with it, whereas the inhabitants of countries where it had

been long in existence seemed to acquire partial immunity against it.

Dr. Belfield concluded his remarks by pointing out the benefit which would arise from a more perfect knowledge of the relation of germs to the etiology of different diseases from a sanitary and economical point of view, the necessity for experimental research in the settlement of questions relating to this subject which were yet undecided, the expense which such investigations necessarily involved, and the material aid given by European governments toward the promotion of such scientific researches, and suggested that our own Government might manifest a laudable ambition in attempts at rivalry in this direction, which at present, however, it seemed little inclined to do.

MEDICAL ETHICS AND ETIQUETTE.

COMMENTARIES ON THE NATIONAL CODE OF ETHICS.

By AUSTIN FLINT, M. D.

First Article.

INTRODUCTORY REMARKS.

It is proposed to contribute a series of articles, to appear in successive numbers of the "New York Medical Journal," each article to consist of a portion of the Code of Ethics adopted by the American Medical Association, with commentaries. The remarks in this number of the journal are introductory to the series.

This announcement might lead one who had given to the subject little or no attention, to ask, "Wherefore the propriety of recognizing the principles of duty applied to medicine as constituting a distinct branch of ethical science?" "Are not the rules in ethics which would govern the practitioner of medicine the same as in other applications?" There are certain fundamental truths which, of course, underlie all possible applications of ethics; but the adaptations to different conditions of human life call for separate consideration. Political ethics and social ethics are recognized different branches of ethical science. Ethics as applied to the medical profession involves adaptations which require to be considered apart from the science as a whole. In various points of view, the practice of medicine, when contrasted with other pursuits, is peculiar. The medical practitioner does not deal with facts and laws having the exactness of those pertaining to physics. In employing means for certain ends, he can not calculate results with mathematical precision. The problems of disease embrace many and varying elements, which can not always be estimated with absolute certainty. They offer a wide scope for the exercise of judgment in the practical applications of medical knowledge. It is by no means easy in all cases for the practitioner himself to judge correctly of the results of his practice; and, for those who are not versed in the study of disease, this is an impossibility; hence, he is often blamed undeservedly, and as often, perhaps, he receives

praise not strictly his due. People can not form a true judgment of the merits of a physician by the character of his work, as can be done with reference to mechanical callings, and even the sister professions of law and theology. The choice of a family doctor is in many instances determined by other circumstances than those which pertain to scientific knowledge or skill, and, as a rule, the relations between the physician and his patients are not purely professional, but involve the ties of friendship, and often affection. In no other profession or calling are extrinsic means available for competition to the same extent as in the practice of medicine, and in no other pursuit are the opportunities so great for ungenerous or unscrupulous advantages. Under these circumstances it is not to be wondered at that physicians are peculiarly sensitive respecting their professional relations and rival practitioners.

Peculiar responsibilities pertain to the practice of medicine, aside from those involved in the treatment of cases of disease. In the exercise of his profession, the physician becomes intimately acquainted with the private character of his patients. Weaknesses, faults, vices, can not be concealed, if not confessed. He can not escape, if he would, knowledge of family secrets. He is exposed to peculiar temptations. Other responsibilities relate to the honor and purity of the profession, the promotion of medical knowledge, the prevention of diseases, and the protection of the public health. The charitable gift of professional services to institutions and to individuals is an obligation which, with certain limitations, is inseparable from the medical profession. Important obligations arise from the opportunities afforded by the relations of physician and patient for advice and aid in overcoming injurious and immoral habits. There are duties connected with the expression of opinions concerning the nature, the probable cause, and the termination of diseases to patients and their friends, with communications respecting the diseases of patients to others, and with testimony given in courts of law. Finally, moral obligations to society are to be fulfilled by the members of the medical profession, individually and collectively, with reference to irregular practitioners, secret nostrums, and all the multitudinous forms of quackery.

The rules of conduct adapted to the peculiarities of medicine constitute medical ethics. These rules have a moral weight. Medical etiquette, on the other hand, consists of the forms to be observed in professional intercourse. These are conventional. They have not the binding force of ethical rules; nevertheless, they claim observance. The medical profession receives not a little ridicule for observing rules of etiquette, but their observance is a protection against not only embarrassment and confusion, but misapprehensions and dissensions, injurious alike to physicians and patients.

If there be ground for a distinct system of ethics applied to medicine, the rules of conduct which the system requires should be codified. A code of ethics adopted by the profession represents the views held by the majority of its members, and is, therefore, binding on all. It is indispensable for the sake of reference whenever differences of opinion arise. It indicates the proper course to those whose

moral perceptions may be defective. It may prove a safeguard against the bias of personal interests. It thus contributes to the purity and dignity of the medical profession. Much would be gained in the popular respect for the profession were the public better acquainted than they are with the ethical rules by which its members assume to be governed. It is, perhaps, a common impression that the objects of a code of medical ethics have exclusive reference to the interests of the medical profession. So far from this, the objects are of far more importance to the public welfare than to physicians. The truth of this statement will be apparent, without argument, to any who will take the trouble to become acquainted with the provisions of the code. The writer may add that, in preparing these articles, he has been actuated by the hope that they may do something in the way of a general diffusion of knowledge on subjects which they who are not members of the medical profession are apt to think do not in the least concern them. These remarks, having reference to the ethics of medicine, will apply measurably to the rules of professional etiquette.

Prior to 1847 the codes of medical ethics which existed in this country were instituted by State or local societies, and in many, probably in most, of the States of the Union there were none. At the convention which resulted in the organization of the American Medical Association, in 1847, a committee, of which the late Isaac Hays was chairman, were instructed to report a code of ethics. This committee reported a code which was adopted unanimously, and from that date it has been recognized as the National Code throughout the whole country. With the single exception of a recent action by the New York State Medical Society, this code has remained without any material additions or modifications. It has had, therefore, the approval of the medical profession of the United States for a period of over thirty-five years. It is but justice to the memory of an excellent English physician to state that the American code is based on that prepared by Thomas Percival, and published in 1803. Credit to Percival was given by Hays, in a note accompanying his report, as follows: "On examining a great number of codes of ethics adopted by different societies in the United States, it was found that they were all based on that by Dr. Percival, and that the phrases of this writer were preserved to a considerable extent in all of them. Believing that language so often examined and adopted must possess the greatest of merits for such a document as the present—clearness and precision—and having no ambition for the honors of authorship, the committee which prepared this code have followed a similar course, and have carefully preserved the words of Percival whenever they convey the precepts it is wished to inculcate." Percival's code of ethics was prepared for a son who was about to engage in medical practice, and who died before its publication. It was dedicated to another son who was engaged in the study of medicine. In its composition, as he says in the dedication, his thoughts were directed to his son, "with the tenderest impulse of paternal love, and not a single moral rule was framed without a secret view to his designation, and an anxious wish that it might influence his future conduct." The following is another quotation from the dedi-

cation: "The relations in which a physician stands to his patients, to his brethren, and to the public, are complicated and multifarious, involving much knowledge of human nature and extensive moral duties. The study of professional ethics, therefore, can not fail to invigorate and enlarge your understanding, while the observance of the duties which they enjoin will soften your manners, expand your affections, and form you to that propriety and dignity of conduct which are essential to the character of a gentleman."

The code of the American Medical Association will form the basis of these articles. The arrangement of topics adopted in that code will be followed, namely: 1st. The duties of physicians to their patients, and the obligations of patients to their physicians. 2d. The duties of physicians to each other and to the profession at large. 3d. The duties of the profession to the public, and the obligations of the public to the profession. The whole series of articles will embrace the entire code, with such comments as may suggest themselves. In a few instances the writer will venture upon critical remarks. In connection with topics which belong to medical ethics will be introduced remarks upon etiquette.

REMARKS ON MEDICAL ETHICS.*

By H. R. HOPKINS, M. D.,

BUFFALO, N. Y.

MR. PRESIDENT: In the growth of the institutions of government, students first notice a generally confessed want of some peculiar service or duty, and then an attempt upon the part of the people to create an organization for the purpose of supplying this service or performing this duty. In this country the operation of this law is to produce corporations more or less permanent as to time, and with functions that in many and varied ways add something to the comfort and well-being of the people at large. At a period early in the history of this State, the year 1806, there was a conviction in the minds of the people that an organized medical profession would contribute to the diffusion of true science, and particularly the knowledge of the healing art. Impelled by this conviction, the people created a corporation known as the Medical Society of the State of New York, and declared that the members of this corporation, and the members of the various local corporations which it embraced, constituted the medical profession of the State. There thus came to be, in this State, an organized or corporate medical profession, and the reason why there was this corporate medical profession was simply because the people thought they would be benefited by the services of such a special class, and therefore made provision for the class, and for its perpetuation.

In these enactments for the organization of the medical profession, the good of the profession was not the end to be attained; the ultimate end sought was the good of the people.

In order that the special class, the profession of medicine, should be at once efficient in its work and conspicuous

among the people, it was granted certain rights and privileges. Chief among these was the right to enact by-laws for its own government and for the control of its own future.

The scope of the grant to enact by-laws, rules, and regulations was very great, but was not unlimited, and the limits were plainly stated by the people at the first, and have since been rigorously maintained. Such rules and regulations must, in general, tend to the diffusion of true science, and particularly the knowledge of the healing art, and in particular must not be contrary to, nor inconsistent with, the laws of this State or of the United States. But within these wide limits the people enacted that the medical profession, in its corporate capacity, should shape and govern its present and future. The efficiency of the profession of to-day demonstrates the wisdom of our fathers and the strength of those institutions which rest in the principle of man's capacity for self-government and self-development.

We are assembled to-day from every part of this Empire State, and we are now engaged in the consideration of a question which, in its ultimate analysis, is simply the question of how far can the individual members of the medical profession of the State of New York be trusted with self-government? How safe is the honor of our profession in the keeping of its individual members? To what extent can the individual be trusted to determine and to set forth what is professional conduct in a given case? or, How far shall the corporate profession anticipate the action and speak for the individual?

The essence of the question is, Are we individually capable of self-government? It is safe to say that few events in the history of the profession have attracted as much attention as did the adoption of the present Code of Ethics by this society.

A construction has been put upon the action of the society and its new code which has stirred the medical profession of the world. For the impression our action in making a new code caused we are not responsible; with the construction put upon that code by various individuals and societies we primarily have little concern. In the consideration of the question we now have before us, it is of the highest importance that we should have only clear ideas regarding the step taken by this society in adopting the new code, and regarding the nature of that code. And in this connection it might be well to remark that, because an impression, opinion, or belief is the prevailing impression, opinion, or belief, it does not by any means follow that the same is in like manner true. Instances in which the majority have held erroneous opinions are too frequent to need individual citation.

We have before seen that chief among the grants of the people to this society was the grant of the right to enact by-laws, rules, and regulations for the government of its members, and we shall do well to recall the limitation placed by the people upon the exercise of this right. Our code of ethics is simply a by-law, rule, or regulation, which we adopt and enforce as an exercise of a corporate right. Such rules are necessarily limited—on the one hand by our sense of the needs of the profession, and on the other by the will of the people, expressed in the term "that they shall not be con-

* Read before the Medical Society of the State of New York, February 6, 1883.

trary to, nor inconsistent with, the laws of the State or of the United States."

The offense of the code of 1882 is found in the sentence beginning with the twenty-ninth line, and reads: "Members of the Medical Society of the State of New York, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine."

In order that we may arrive at a correct appreciation of the spirit and the letter of this sentence, it is necessary, first, to come to an understanding of what it means "to be entitled to all the rights and privileges of the practice of physic and surgery under the laws of this State," or, rather, if one so entitled has the right to the consulting attendance of others similarly authorized. The first question is, Mr. President, whether you have the right to call upon men bearing the same commission as yourself for their attendance in consultation, when such attendance is desired by your patients or by yourself. If you, Mr. President, have that right, then I and many others have the same right; and we then come to our second question, Where did we get this right? Simple as these questions may seem, upon their answer rests the whole matter that has taken so much of the time and attention of the profession of this land during the last year. That worthy men stand on opposing sides is simply because of the different views held concerning the nature and the source of the peculiar rights of the physician.

To my mind there is only one answer that can be given to these questions, and that is, The right to practice physic and surgery includes the right to consulting attendance of physicians, and these rights come to individual members of the medical profession from the people. To men holding this view of the nature and source of the rights of the physicians of this State the code could not refer to consultations in language much different from that above used, and still be in accord with the laws of the State. To men who maintain that a physician has the right to withhold consulting attendance from another because he does not like him, or does not like the color of his gloves or the fit of his coat, or because their opinions regarding the nature of disease or the remedial action of drugs differ—to such the language of the code of 1882 is quite objectionable, and from their premises should certainly be changed. But are these gentlemen sure their premises are perfectly in accordance with the facts? In case this sentence of the code should be changed to make it accord with expressed sentiments of the various medical societies which have seen fit to resolve upon this matter, it would read:

Members of the Medical Society of the State of New York, and of the medical societies in affiliation therewith, shall not meet in consultation legally qualified practitioners of medicine who hold views usually held by homœopathic or eclectic physicians. The code of 1849 was not worded in just this way, but the practice under that code is fairly expressed by the restrictive clause just quoted. We should not be afraid to show our colors on this question, and the friends of the present code have the right to ask its opposers to support a code which shall plainly set forth the principles for which they declaim. That their views are fairly presented above we maintain, and would ask attention

to a few points of criticism upon such a rule of conduct. Although this supposed code differs in its letter from that of 1849, the spirit is the same in each, and for purposes of criticism they may be considered as one. Mr. President, such a regulation could not be enacted and enforced, for the reason that it would not only be inconsistent with the laws of the State, but would be contrary to them, and in direct violation, or attempt to violate, the acts of 1857 and of 1865, creating the homœopathic and eclectic professions.

In these acts the people decreed that the members of these societies were physicians entitled to all the rights and privileges of the practice of physic and surgery under the laws of this State, while the code of 1849 and our supposed code assert that they are not physicians, and are not entitled to the rights peculiar to physicians.

Since April 13, 1857, the code of ethics of this society has been illegal and void, and any attempt on our part to enforce its provisions would have been to make war upon the people of the State of New York. This statement is made without reservation or qualification, and I challenge any man here at this time, or at any time, to show its incorrectness. The people of this State, for their own purposes, created the corporations known as the State and County Medical Societies, and declared that their members should have all the rights of physicians; and the people (perhaps not with the same wisdom) created the homœopathic and eclectic societies, and similarly decreed that their members should have and exercise all the rights of physicians under the laws of the State. No matter whether it suits our taste or whether it does not, whether it seems to us wise or unwise, whether we like it or whether we do not like it, this is the case, and our code of ethics, if we would have one, must recognize the fact, and bow before the will of the sovereign people. We must remember that we exist by the will of the people for the good of the people, and that it does not rest with us to say when, or for what cause, the people have forfeited their rights to our services; and when the corporate medical profession, when this society, announces that its members may not meet in consultation legally qualified practitioners, we attempt to dictate to the people, to sit in judgment upon the wisdom of their legislative enactments; we arrogate to ourselves powers that in no manner or degree belong to us, and we do that which we can ill afford to do—we make our profession ridiculous.

There are men in our profession who do not seem to grasp the meaning of the restriction placed upon the rights of State and county societies to enact by-laws, rules, and regulations. We have a vague and general conception that such by-laws, rules, and regulations must not be opposed to the laws of the State, whereas the fact is, they "must not be contrary to nor inconsistent with" such laws; and in this language the term "not be contrary to" is strong enough, but the weakest part of the phrase, and may be considered to apply, as it were, to the letter of the law, while the strength of the restriction is found in the term "nor inconsistent with." The former may be evaded much easier than the latter, which is far more sweeping and comprehensive, and includes not only the letter, but the more subtle spirit as well. We must not forget, therefore, that the people are far

more strict with us than that our rules and regulations should not be contrary to law; and hence it is that, if we would avoid the legal inconsistency which would invalidate our rules, those rules must either not mention the subject of consultations, or must treat that question as it is treated by the code of 1882. We have now practically before us these questions: What are the rights of physicians in the matter of consultations? and What was the operation of the laws of 1857 and 1865 upon the members of the homœopathic and eclectic medical societies created thereby? That the true answer to these questions is found in the code of 1882 I think all unbiased people will agree, and we should not forget that, if this answer is true, it will be none the less so even if this society votes to the contrary.

In the foregoing I have attempted to make prominent the relations of the profession to the medical law of the State, as well as the relations of the profession to the people—the law-making power.

This is done for the reason that this society, the exponent of the profession, undertakes to declare to the world through our code of ethics what are those relations, and it is, before all things, important that the utterances of this society upon this subject should be such as to need no revision.

At first glance, it would be supposed that there could not by any possibility be two opinions among physicians upon the questions involved in this issue; that the elements were so few and so simple that there could be no question about their interpretation. But the fact is, that the medical profession of the whole civilized world is to-day *in two camps*, anxiously watching the deliberations of this society upon this question.

It may not come amiss to spend a moment in hasty review of some of the utterances of the fathers of the profession, and see what light those views will throw upon this question.

Such a review is more particularly necessary at this time for the reason that the opposers of our present code have done much to create the impression that the adoption of such code was in every way revolutionary, and opposed to all the traditions of the profession; while the fact is that one can not make even a cursory study of the writings of the great minds of the early days of this society without being struck with the fact that those men foresaw the dangers and trials of the present, and time after time warned the profession, in no uncertain tones, against the very dangers which now menace our future.

The principles and practice of the best men in this society found expression, in the year 1823, in a *System of Medical Ethics*. This system was the result of the labors of a committee of the most eminent medical men of their times, who were appointed February 8, 1821, were ordered to sit again July 5, 1822, and who reported February 6, 1823—just sixty years ago this day. This system was the exponent and guide of the profession from the time of its adoption until the year 1849, when it was supplanted by the code of the American Medical Association.

I would ask the gentlemen who oppose the code of 1882 to construe the acts of 1857 and 1865 in the light of

this provision of our primitive code. Section 8—*Specifications of Medical Ethics in Practice*—says:

“Honor and justice particularly forbid a medical practitioner infringing upon the rights of another *who is legally accredited*, and whose character is not impeached by public opinion, or civil or medical authority, whether he be a native, or a stranger settled in the country. There is no difference between physicians but such as result from their personal talents, medical acquirements or experience; and the public, from the services they receive, are the natural judges of their intellectual advantages.”

I recommend the careful study of this condensed sermon on ethics to the men who have started the cry that the code of 1882 is disloyal to the profession. I wish it could be read in the ears of every physician in this State or country who has seen fit to impugn the motives of the members of the special committee who had the courage to recommend the unpopular truth, and earnestly hope that every member of this society who has a vote upon this question will weigh well these lines of wisdom, and learn from them what the fathers thought concerning the relations which should exist between legally qualified physicians.

In my judgment, the code of 1882 is simply a construction of the existing medical law of the State in the light of the principles of our primitive system of ethics. And I further contend that the wholesale distribution of medical diplomas, sought and valued because they are licenses to practice, which has been going on for the past half-century, has not given us a profession in any way superior, in regard to personal dignity, elevation of character, or professional pride and ambition, to the medical profession of the early years of this society; that the calm, judicious, and unbiased utterances of such men as Romayne, Wilson, Rodgers, Stearns, Manly, and Pascalis are to-day safe and competent guides in matters of ethics. The American Medical Association was organized for the purpose of raising the standard of medical education and attainment in this country, and for years the best men in that association were appointed upon committees, and made annual reports upon the various questions pertaining to matters of medical education and ethics. In 1852, the Committee on Medical Education were fortunate in having for their chairman Dr. Worthington Hooker, of New Haven, who presented to the association a most elaborate and thoughtful report.

Such an impression was made by this report that this society ordered the complete paper republished in its proceedings, and it appears in the *Transactions for 1852*.

Much of the thought of this report is pertinent to our present consideration, and I would ask your attention to a few sentences, and would remind you that they stand indorsed by the combined strength of the national and our own State society.

“In connection with the subject of organization, it becomes an interesting inquiry, *What should be the basis of the profession?* It is manifest that it can not be the same in this that it is in some other countries. It must be conformed to the genius of our institutions, it must recognize most fully the voluntary principle. Any plan which does not recognize this can not succeed. It is in vain to

attempt the enforcement of any direct legal restriction upon the people in regard to medicines.

"That there should be some laws in relation to the medical profession there is no question. In the opinion of the committee, the object of these laws should be simply this: *to give protection to those measures which are calculated to secure to the community a well-educated body of physicians.* Everything inconsistent with the attainment of this object should be discarded. The medical profession should be a single body of men without any set of opinions. And the ground of admission to their ranks should have no reference to opinions; but there should be the greatest latitude in this respect. Character and education should furnish the only basis of membership. We are persuaded that if the profession as a whole should take this view of the subject, we should stand in a much better position before the public than we now do. We should then be able to propose to the community the question, clean and stripped of all incidental and embarrassing considerations, whether they would sustain an educated or an uneducated profession. But, when other grounds are taken, and opinions are made in any degree the basis of admission or expulsion, we lose this respect and confidence, for we enter into competition with opinionists of every grade, and upon their own level. At this moment the strife between the regular profession and other self-constituted medical bodies is regarded, by even sensible men in the community, as being for the most part a war of opinions.

"And some ground is given them for this view of the subject by occasional acts by individuals, or even by some of our associations. . . .

"If this ground should be distinctly and firmly taken by the great body of medical men, we should then stand before our legislatures and the community upon a basis which would commend itself to the judgment of every reasonable man. But any act on the part of physicians which trenches in any degree upon freedom of opinion, prevents our holding successfully this broad ground before the public."

Mr. President, I have endeavored to set forth reasons why the code of 1882 is worthy of our support, in that its utterances are in harmony with the letter and the spirit of the medical law of the State; and I would now maintain that the principles enunciated in the quotation just made support the assertion that the action of this society in adopting its present code was wise and expedient.

We know full well that it is one thing to feel sure that a certain declaration of principle is well founded, incapable of controversion, and quite another matter, to be sure, that it is expedient at this time to formally set forth and publish such a declaration. A conclusion upon the latter question includes the consideration of all the facts comprised in the former, and many more besides; but one can not study the writings of the leading men in our profession—the men who have devoted so much of their talents to the organization and maintenance of the various corporate associations of the profession, State and national—associations whose objects are the up-building of the professional character, the attempt to realize the ideal, the good physician; one can not learn of these old masters and not be convinced that the

policy of the profession of this State, as shaped by the code of 1849, has been based upon false premises, has been untrue to the genius of our art and of our institutions, has not commended itself to the judgment of reasonable men, and that its reformation is called for by every argument of fidelity, justice, and expediency.

Mr. President, I would close with the thought implied in the word "expedient." Is it *expedient* that the profession of this State should shape its policy by the code of 1882?

My mind is absolutely overwhelmed in the attempt to grasp the issues involved in this question. The facts involved in the relations which should exist between the individual members of the profession; between the members of the profession and their patients; between the profession and the people who make the State; between the profession of to-day and the profession of the future; between the science of to-day, its imperfections, its limitations, its undevelopment, and the science of the future, with its full fruition, its glorious realities—all these are involved in this question of expediency.

Never in the history of this society has a more momentous question come up for its consideration and decision; and, as that decision is given, will the profession of this State, like the chosen people of old, this day go over Jordan, or turn back to wander in the wilderness? Men have said, and I have blamed them for it, that the code of 1882 is revolutionary; but they are right; it is revolutionary, and the profession under its guidance would be like the traveler who has been following a will-o'-the-wisp, but at length discerns the beacon light of a mansion where he fain would be, and resolutely sets his face in that direction and determines to brave all dangers, to overcome all obstacles, to surmount all difficulties, that after many trials he may rest and be refreshed in the mansion of many delights—the intelligent confidence of a free people.

TRICHINIASIS IN ITS RELATION TO PUBLIC HEALTH AND NATIONAL ECONOMY.

By FRANK S. BILLINGS, VET. SURG.,

BOSTON.

Second Article.

TRICHINIASIS IN SWINE.

As has been previously mentioned, trichinæ were first discovered in the flesh of the hog by Leidy, in 1847.

It is to German observers that we must look almost entirely for any statistical statements with reference to the percental infection of swine with trichinæ; for in no other country is there, at present, anything approaching a systematic examination of pork, and even in Germany there is still much room for improvement. To make such statistics really valuable, it is absolutely necessary that the law should require all hogs to be examined for trichinæ, and they should be examined before the carcasses are cut up for distribution or packing; and, again, the pillars of the diaphragm should invariably be the part examined, while the examination may

also extend to other parts. Unless there is uniformity among all observers as to the part of the hog selected for examination, all comparison of the results obtained is next to useless. As has been shown, the pillars of the diaphragm are that portion of the hog which is earliest and most richly infected with trichinæ; and, as there is no evidence that this part has been selected by German inspectors as the portion to be invariably examined, I must say that I think the ratio of infection would be found still larger were this part examined.

The best sources from which to obtain German statistics are: Virchow's "Archiv," "Vierteljahrsschrift f. gerichtl. Medicin," "Deutsche Zeitschrift f. Thiermedizin," "Veterinair. Berichte" of Hanover and Saxony, "Archiv f. Thierheilkunde," and the "Mittheilungen a. d. thierärztlichen Praxis d. preussischen Staate."

From these sources have been compiled the following:

Rostock. Petri reports:

Percentage 1: 3,543.

For Braunschweig, Uhde reports whole number examined between 1866 and 1880, 111,806 hogs; trichinous, 29.

1866-1867 there was found 1 hog, of every 6,700 examined, trichinous.

Total.... 12,816,831

6,045

Percentage, 1: 1,845.

The Prussian report for 1880 deserves some special consideration.

The percentage of trichiniasis among hogs has, we see, constantly increased with each year since 1876. In 1879 it was 1:1,632, and in 1880, 1:1,460, which must be attributed either to greater exactness among the examiners, or to the numerical augmentation of the latter. In Berlin, the per cent. of infection was (1880) 1:1,247, while in Posen,

of the number examined, 1:138 was found trichinous. No endeavor, of any moment, has as yet been made in Germany to arrive at the original source from which hogs become infected. Three hundred and twenty-nine cases of trichiniasis among human beings, and four deaths, are recorded. These cases were all traced to the consumption of improperly cooked, or insufficiently examined, pork. In Berlin there were but sixteen cases of human trichiniasis, a much smaller number than in any previous years, which is attributed to the greater stringency with which the examinations are carried out. One of these cases is instructive from the fact that the person who died consumed a piece of raw pork known to be trichinous, in order to show his disbelief in the danger from eating such meat. Of examinations of American pork this report says: Three thousand and thirty infected pieces were found.

Such an examination of American pork is absolutely without statistical value, as no one knows how many such pieces come from the same hog, for at least two sides, two shoulders, and two hams could come from one and the same hog in the same lot or consignment of smoked or salted American pork. The report says: "No examiner should be expected to investigate more than twenty sides a day." (?)

In Schleswig, of 783 "amerikanischen Rouladen," 8 were found trichinous; of 1,952 sides, 64; of 3,900 hams, 66; and of 13 shoulders, 3. At Stettin, 72,230 American sides were examined, and 1,124 were found trichinous.

The number of swine infected with *cysticercus celluloseæ*, the embryo of the human tape-worm, *Tænia solium*, is worthy of American consideration.

From Hamburg, Germany, we have the following instructive, as well as suggestive, statistics:

1878..	Of 35,510 American hams examined,	1,087 trichinous.
1878..	Of 14,003 " sides	85 "
1878..	Of 17,113 European hams	3 "
1878..	Of 222 " sides and 10,838 hogs examined,	none "
1879..	Of 79,864 American hams examined,	1,087 "
1879..	Of 22,749 " sides and shoulders examined,	196 "
1879..	Of 28,710 European hams examined,	2 "
1879..	Of 16,204 " hogs	1 "
1880..	Of 55,008 American hams	566 "
1880..	Of 25,580 " sides	270 "
1880..	Of 49,943 European hams, sides, and hogs examined,	none "

At Blankenburg, from 1864 to 1865, 7:8,000 hogs examined, and but 1 found trichinous.

At Hanover, from 1865 to 1866, 18,656 hogs examined, and 12 found trichinous.

At Frankfort on the Oder, 8,000 hogs examined (1875 to 1876), and 4 found infected.

At Copenhagen, 1867, 8,174 examined, and 15 trichinous.

At Charkov (Russia), 1876, 3,550 examined, and 5 trichinous.

These statistics could be multiplied *ad lib.*, but they are sufficient to demonstrate the results of continental examinations. It is to be greatly regretted that no other

country gives any statistics whatever as to the examinations of pork for trichinæ.

TRICHINÆ IN AMERICAN PORK.

The question of the percental infection of American hogs with trichinæ is one of immense importance, not only from an economical stand-point, but from that of public health as well. Before discussing the various opinions which exist upon this point, it will be as well to consider the results of a few examinations aside from those quoted from the Hamburg reports:

At Rostock, Germany, 12 of 622 American sides were found trichinous.

At Gothenburg, 8 out of 210.

At Elbing, 2 per cent. of the pieces examined.

At Schleswig-Holstein, of 5,673 pieces, 47 infected.

Professor Mueller, of the Berlin Veterinary College, wrote me in December, 1880, that of 88 live American hogs—part of a shipment—that had been sent to Dresden, the inspector there found 14 trichinous.

Dr. Loring* says: "I do not know that Germany or France has even examined for this disease in live hogs.

"Where ignorance is bliss 'tis folly to be wise."

The foregoing was reported by me in American papers at the time, and subsequently in the Report of the Imperial Board of Health of Germany, and several German medical reviews; and could have been as well known to our agricultural department as the presence of pleuro-pneumonia in the District of Columbia, a fact ocular demonstration of diseased lungs could scarcely force upon eyes blurred by political blindness.

At Turin, Italy, February, 1879, 4 per cent. of a lot of Cincinnati hams were found trichinous, which led to governmental restrictions being placed upon further importations.

The continual recurrence of such facts has caused a more or less strong feeling on the Continent of Europe against the use of American pork—a feeling which nationalism and the public prints have fostered to the fullest extent.

The result has been that in several countries restrictive measures have been introduced regulating the importation of American pork which no one with the true facts before his mind can deny the justice of. Naturally, the old adage, "touch a man's pocket and you touch his heart," found illustration upon this side of the Atlantic. It was protection, but justified, carried home to the American producers for more sensible protection than the American principle, which utterly ignores the masses, the consumers, for the benefit of the few.

An embargo against the importation of American pork on account of trichinæ is especially justifiable, as it is largely the masses—viz., the poorer classes—that are consumers of that article.

This measure tends to protect the poor man's health, while American protection tends to make the cost of living as severe as possible.

The result has been: The pork interest became alarmed and called upon our Government to help them.

Our consuls, all over Europe, were requested to make inquiries as to the true nature of these reports, and to notify our Government as to the results of their examinations. One thing in their reports is very manifest: they went for information chiefly to importers, persons interested nearly as much as the American exporter. It is not my purpose to refer to these reports in detail, but they displayed fully as much patriotic defense of the non-trichinous condition of American pork as the Continentals did in the opposite direction. Unfortunately, Europeans had some figures to help their case that were hard to get over. An earnest desire to arrive at the truth of the matter pervaded neither our representatives at home nor abroad.

As with contagious pleuro-pneumonia of our cattle, so with trichiniasis of our hogs. Our Government adopted a prevaricating and cowardly course; it sought to "bluff down" the results of foreign examinations, and either did not seek to know the results, or ignored home examinations.

In the face of a Report of the State Board of Health of Massachusetts—numerous copies of which were sent to Washington, which contained a paper on the subject of trichiniasis, and statistics of the examination of the largest number of hogs which had, until then, been made in this country—the State Department at Washington published a singular document, which requires our attention.

Clauses 8, 9, and 10 read as follows:

8. "That the percentage of American hogs infected with trichinæ is, in all probability, by reason of the superiority of the breed, and feeding, much less than that among the hogs of any other country."

(a) When a government through any of its departments makes a statement with reference to any question of so grave importance as trichinæ in our pork, it should have some stronger grounds than a "probability" upon which to support its assertions.

There are no records of the Government ever having authorized any examination of American hogs for trichinæ.

(b) Who ever heard of the breed of hogs having any influence upon trichinæ-infection? Who was the learned informant of our Government in this matter?

Superiority of feeding, so far as grain is concerned, has but little influence upon trichinæ-infection, if any at all, so long as hogs are allowed to root in refuse or run at large.

Such assertions can not be justifiably made until we know the original source from which hogs derive trichinæ.

With reference to "corn-feeding," Dr. Jansen T. Payne* makes some assertions which are of interest, but equally ridiculous with the foregoing, and show very little study of the trichinæ question. He says, of the hogs he examined at New Orleans: "All the hogs infected with trichinæ ARE CORN-FED ANIMALS; no mast-fed animals were found to be infected," which is as much as saying that corn-feeding is a cause of trichiniasis—an assertion, as an investigator, I should be ashamed to have to father. Wild hogs that are not corn-fed have been found infected with trichinæ.

* Letter to Health Congress.

* Ninth Annual Meeting of American Public Health Association.

9. "That freedom from trichiniasis of the two great pork-consuming centers of the West, Chicago and Cincinnati, furnishes the strongest possible evidence of the purity of American pork. In Chicago, of 40,000 deaths, with causes reported, for a series of years, only two were from trichiniasis. During the same time none were reported in Cincinnati."

(c) Does the author mean that the people of these two cities consume more pork than those of New York, or the packing-houses?

(d) The consumption of pork as food bears no relation whatever to the number of cases of trichiniasis among people. One might almost be justified in saying that the consumption of known trichinous pork did not.

The way it is eaten does, however. Well cooked or not, that is the question.

Clause 10 indorses the last assertion:

"The reported cases of trichiniasis among human beings have resulted from eating uncooked pork," etc.

Hundreds of cases of trichinous infection are either so slight as to escape the attention of the doctors, or do not cause inconvenience enough to necessitate calling a doctor, or, as will be shown, if severe, are mistaken for something else. The tone of the governmental argument is false from the bottom; as to eating uncooked pork, many slurs are made at our German citizens in this regard, while we, of English descent, fail to see that carnivorousness and its results are common to all people; the German indulges in raw, spiced, or smoked pork, and from it derives trichiniasis; the American eats raw or uncooked beef, and derives a tape-worm. Comment is unnecessary, the only difference being, the German runs a greater risk of being sick or losing his life; the act is the same.

(To be concluded.)

Book Notices.

Pestilentia in Nummis. Geschichte der grossen Volkskrankheiten in numismatischen Documenten. Ein Beitrag zur Geschichte der Medicin und der Cultur. Von Dr. L. PERFFER und C. RULAND. Mit zwei Tafeln-Abbildungen in Lichtdruck. Tübingen: H. Laupp, 1882. Pp. x 189. [From B. Westermann & Co. Price, \$2.20.]

SELDOM, if ever, has a book of this character been placed before the medical profession. Viewing it from a numismatical stand-point, it is work of decided merit, embracing, as it does, a description of every medal known to have been produced in commemoration of the great epidemics which have ravaged the world since 1505.
